At very high densities, electrons react with protons to form neutron rich matter. This material is central to many fundamental questions in nuclear physics and astrophysics. Moreover, neutron rich matter is being studied with an extraordinary variety of new tools such as the Facility for Rare Isotope Beams (FRIB) and the Laser Interferometer Gravitational Wave Observatory (LIGO). We describe the Lead Radius Experiment (PREX) that uses parity violating electron scattering to measure the neutron radius of ²⁰⁸Pb. This has important implications for neutron stars and their crusts. We discuss X-ray observations of neutron star radii. These also have important implications for neutron rich matter. Gravitational waves (GW) open a new window on neutron rich matter. They come from sources such as neutron star mergers, rotating neutron star mountains, and collective r-mode oscillations. Using large scale molecular dynamics simulations, we find neutron star crust to be very strong. It can support mountains on rotating neutron stars large enough to generate detectable gravitational waves. Finally, neutrinos from core collapse supernovae (SN) provide another, qualitatively different probe of neutron rich matter. Neutrinos escape from the surface of last scattering known as the neutrino-sphere. This is a low density warm gas of neutron rich matter. Neutrino-sphere conditions can be simulated in the laboratory with heavy ion collisions. Observations of neutrinos can probe nucleosyntheses in SN. We believe that combing astronomical observations using photons, GW, and neutrinos, with laboratory experiments on nuclei, heavy ion collisions, and radioactive beams will fundamentally advance our knowledge of compact objects in the heavens, the dense phases of QCD, the origin of the elements, and of neutron rich matter.

1. Introduction

Multi-messenger astronomy observes matter under extreme conditions. In this paper we describe how electromagnetic, gravitational wave, and neutrino astronomy, along with laboratory experiments, provide complimentary information on neutron rich matter. Compress almost anything to very high densities and electrons react with protons to form neutron rich matter. This material is at the heart of many fundamental questions in Nuclear Physics and Astrophysics.

- What are the high density phases of QCD?
- Where did the chemical elements come from?
- What is the structure of many compact and energetic objects in the heavens, and what determines their electromagnetic, neutrino, and gravitational-wave radiations?

Furthermore, neutron rich matter is being studied with an extraordinary variety of new tools such as the Facility for Rare Isotope Beams (FRIB), a heavy ion accelerator to be built at Michigan State University [1], and the Laser Interferometer Gravitational Wave Observatory (LIGO) [2]. Indeed there are many, qualitatively different, probes of neutron rich matter including precision laboratory measurements on stable nuclei and experiments with neutron rich radioactive beams. While astrophysical observations probe neutron rich matter with electromagnetic radiation, neutrinos, and gravitational waves. In this paper we give brief examples of how neutron rich matter is being studied with these extraordinarily different probes.

We are interested in neutron rich matter over a tremendous range of densities and temperatures were it can be a gas, a liquid, a solid, a plasma, a liquid crystal, a superconductor, a superfluid, a color superconductor, etc. Neutron rich matter is a remarkably versatile material. The liquid crystal phases are known as nuclear pasta and arise because of coulomb frustration [3, 4]. Pasta is expected at the base of the crust in a neutron star and can involve complex shapes such as long rods ("spaghetti") or flat plates ("lasagna"). Neutrinos in core collapse supernovae may scatter coherently from these shapes (neutrino pasta scattering) because the shapes have sizes comparable to the neutrino wavelength [5]. An example of nuclear pasta is shown in Fig. 1.

At very high densities, neutron rich matter should form exotic quark and gluon phases. Asymptotic freedom in QCD implies that at high densities, quarks will be nearly free. Under these conditions, attractive gluon exchange interactions should pair the quarks into a color superconductor [7]. Multi-messenger astronomy is, at present, the only way to observe cold dense matter and search for a color superconductor. It can not be created in the laboratory. Although heavy ion collisions can produce high densities, there is no way to get the entropy out and produce low temperatures. Thus hot dense matter can be studied in the laboratory, but not cold dense matter. Indeed a very interesting strongly interacting quark gluon plasma has been observed at the Relativistic Heavy Ion Collider (RHIC) [8]. This very hot material forms a nearly perfect fluid with a low shear viscosity.

In this paper we focus on some of the simpler gas, solid, and liquid phases of neutron rich matter. In Section 2 we describe a precision laboratory experiment called PREX to measure the neutron radius of ²⁰⁸Pb. Nuclei are liquid drops, so PREX and many other laboratory experiments probe the *liquid* phase of neutron rich matter. In astrophysics, electromagnetic, gravitational wave, and neutrino probes can observe different phases of neutron rich matter because the probes have

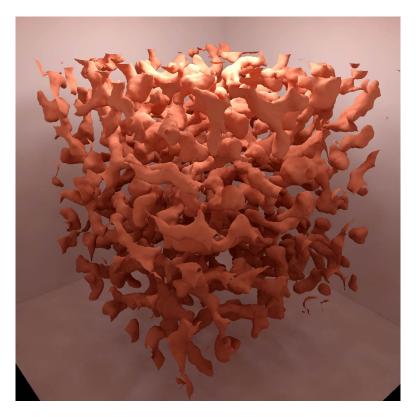

Figure 1: Surfaces of proton density for a pasta configuration of neutron rich matter at a baryon density of 0.05 fm^{-3} . This is from a semiclassical molecular dynamics simulation with 100,000 nucleons [6].

very different mean free paths. In Section 3 we describe electromagnetic observations of neutron star radii. In Section 4 we discuss gravitational waves from neutron star mergers that are produced by the energetic motions of dense *liquid* phase neutron rich matter. In addition, continuous gravitational waves can be produced by "mountains" of *solid* neutron rich matter on rapidly rotating stars. In Section 5 we discuss neutrinos from core collapse supernovae. The neutrinos are emitted from a low density warm *gas* of neutron rich matter. We conclude in Section 6.

2. Laboratory probes of neutron rich matter

Neutron rich matter can be studied in the laboratory. Hot and or dense matter can be formed in heavy ion collisions, while more neutron rich conditions can be accessed with radioactive beams. In addition precise experiments are possible on stable neutron rich nuclei. We give one example, the Lead Radius Experiment (PREX) [9] accurately measures the neutron radius in ²⁰⁸Pb with parity violating electron scattering [10]. This has many implications for nuclear structure, astrophysics, atomic parity violation, and low energy tests of the standard model.

2.1 Introduction to neutron densities and neutron radii

Nuclear charge densities have been accurately measured with electron scattering and have become our picture of the atomic nucleus, see for example ref. [11]. These measurements have had an enormous impact. In contrast, our knowledge of neutron densities comes primarily from

hadron scattering experiments involving for example pions [12], protons [13, 14, 15], or antiprotons [16, 17]. See also ref. [18] for a beautiful measurement of the dipole polarizability. However, the interpretation of hadron scattering experiments is model dependent because of uncertainties in the strong interactions.

Parity violating electron scattering provides a model independent probe of neutron densities that is free from most strong interaction uncertainties. This is because the weak charge of a neutron is much larger than that of a proton [19]. Therefore the Z^0 boson, that carries the weak force, couples primarily to neutrons. In Born approximation, the parity violating asymmetry A_{pv} , the fractional difference in cross sections for positive and negative helicity electrons, is proportional to the weak form factor. This is very close to the Fourier transform of the neutron density. Therefore the neutron density can be extracted from an electro-weak measurement [19]. Many details of a practical parity violating experiment to measure neutron densities have been discussed in a long paper [10].

The neutron radius of 208 Pb, R_n , has important implications for astrophysics. There is a strong correlation between R_n and the pressure of neutron matter P at densities near 0.1 fm⁻³ (about 2/3 of nuclear density) [21]. A larger P will push neutrons out against surface tension and increase R_n . Therefore measuring R_n constrains the equation of state (EOS) — pressure as a function of density — of neutron matter.

Recently Hebeler et al. [22] used chiral perturbation theory to calculate the EOS of neutron matter including important contributions from very interesting three neutron forces. We have some information on isospin 1/2 three nucleon forces from mass 3 nuclei (3 He, 3 H) and proton-deuteron scattering. However, our experimental information on three neutron forces is limited. From their EOS, they predict $R_n - R_p = 0.17 \pm 0.03$ fm. Here R_p is the known proton radius of 208 Pb. Monte Carlo calculations by Carlson et al. also find sensitivity to three neutron forces [23]. Therefore, measuring R_n provides an important check of fundamental neutron matter calculations, and constrains three neutron forces.

The correlation between R_n and the radius of a neutron star r_{NS} is also very interesting [24]. In general, a larger R_n implies a stiffer EOS, with a larger pressure, that will also suggest r_{NS} is larger. Note that this correlation is between objects that differ in size by 18 orders of magnitude from $R_n \approx 5.5$ fm to $r_{NS} \approx 10$ km. We discuss observations of r_{NS} in Section 3.

The EOS of neutron matter is closely related to the symmetry energy S. This describes how the energy of nuclear matter rises as one goes away from equal numbers of neutrons and protons. There is a strong correlation between R_n and the density dependence of the symmetry energy dS/dn, with n the baryon density. The symmetry energy can be probed in heavy ion collisions [25]. For example, dS/dn has been extracted from isospin diffusion data [26] using a transport model.

The symmetry energy S helps determine the composition of a neutron star. A large S, at high density, implies a large proton fraction Y_p that will allow the direct URCA process of rapid neutrino cooling. If $R_n - R_p$ is large, it is likely that massive neutron stars will cool quickly by direct URCA [27]. In addition, the transition density from solid neutron star crust to the liquid interior is strongly correlated with $R_n - R_p$ [28].

Finally, atomic parity violation (APV) is sensitive to R_n [29],[30],[10]. Parity violation involves the overlap of atomic electrons with the weak charge of the nucleus, and this is primarily carried by the neutrons. Furthermore, because of relativistic effects the electronic wave function

can vary rapidly over the nucleus. Therefore, the APV signal depends on where the neutrons are and on R_n . A future low energy test of the standard model may involve the combination of a precise APV experiment along with PV electron scattering to constrain R_n . Alternatively, measuring APV for a range of isotopes can provide information on neutron densities [31].

2.2 The Lead Radius Experiment (PREX)

We now discuss a direct measurement of R_n . Parity violation provides a model independent probe of neutrons, because the Z^0 boson couples to the weak charge, and the weak charge of a proton $Q_W^p = 1 - 4\sin^2\Theta_W \approx 0.05$ is much smaller than the weak charge of a neutron $Q_W^n = -1$. Here Θ_W is the weak mixing angle.

The Lead Radius Experiment (PREX) at Jefferson Laboratory [9] measures the parity violating asymmetry A_{pv} for elastic electron scattering from ²⁰⁸Pb. The asymmetry A_{pv} is the fractional cross section difference for scattering positive (+), or negative (-), helicity electrons,

$$A_{pv} = \frac{\frac{d\sigma}{d\Omega}|_{+} - \frac{d\sigma}{d\Omega}|_{-}}{\frac{d\sigma}{d\Omega}|_{+} + \frac{d\sigma}{d\Omega}|_{-}}.$$
(2.1)

In Born approximation, A_{pv} arrises from the interference of a weak amplitude of order the Fermi constant G_F , and an electromagnetic amplitude of order the fine structure constant α over the square of the momentum transfer q^2 [19],

$$A_{pv} \approx \frac{G_F q^2 F_W(q^2)}{2\pi\alpha\sqrt{2}F_{ch}(q^2)}$$
 (2.2)

Here the weak form factor $F_W(q^2)$ is the Fourier transform of the weak charge density $\rho_W(r)$, that is essentially the neutron density, $F_W(q^2) = \int d^3r \frac{\sin(qr)}{qr} \rho_W(r)$, see Fig. 2.

Likewise, the electromagnetic form factor $F_{ch}(q^2)$ is the Fourier transform of the (electromagnetic) charge density $\rho_{ch}(r)$. This is known from elastic electron scattering [11]. Therefore, measuring A_{pv} as a function of q allows one to map out the neutron density $\rho_n(r)$. Note that, for a heavy nucleus, there are important corrections to Eq. 2.2 from Coulomb distortions. However, these have been calculated exactly by solving the Dirac equation for an electron moving in both a Coulomb potential of order 25 MeV and a weak axial vector potential of order electron volts [32]. Therefore, even with Coulomb distortions, one can accurately determine neutron densities. Note that this purely electroweak reaction is free from most strong interaction uncertainties.

The PREX experiment measures A_{pv} for 1.05 GeV electrons elastically scattered from ²⁰⁸Pb at laboratory angles near five degrees. The first measurement yielded $A_{pv} = 0.656 \pm 0.060$ (statitistical) ± 0.014 (systematic) ppm [9]. From this the rms neutron radius R_n minus proton radius R_p for ²⁰⁸Pb was found to be $R_n - R_p = 0.33^{+0.16}_{-0.18}$ fm. See also ref. [33] for more details of this analyis. A second PREX run is now approved to accumulate more statistics and reach the original goal of determining R_n to 1% (± 0.05 fm).

In addition to PREX, many other parity violating measurements of neutron densities are possible, see for example [34]. Measuring R_n in ⁴⁸Ca is particularly attractive. First, ⁴⁸Ca has a higher experimental figure of merit than ²⁰⁸Pb. Therefore a ⁴⁸Ca measurement may take less beam time than for ²⁰⁸Pb. Not only does ⁴⁸Ca have a large neutron excess, it is also relatively light. With only

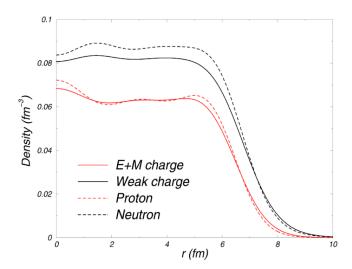

Figure 2: Densities of ²⁰⁸Pb in a relativistic mean field model [20]. The lower dashed (red) curve shows the point proton density while the upper dashed (black) curve is the neutron density. The (electromagnetic) charge density is the lower solid (red) curve while the upper solid (black) curve shows the weak charge density that is measured in the PREX experiment.

48 nucleons, microscopic coupled cluster calculations [35], or no core shell model calculations [36], may be feasible for 48 Ca that are presently not feasible for 208 Pb. Note that these microscopic calculations may have important contributions from three nucleon forces. This will allow one to make microscopic predictions for the neutron density and relate a measured R_n to three nucleon forces and in particular to very interesting three neutron forces.

3. Electromagnetic observations of neutron star radii

Neutron stars are collapsed stellar objects that are formed in supernova explosions. They are more massive than the sun but have radii of order 10 km. This makes them an extraordinary 18 orders of magnitude larger than a ²⁰⁸Pb nucleus and 55 orders of magnitude more massive. There is a very interesting relationship between the neutron radius of ²⁰⁸Pb, of order 6 fm, and the radius of a neutron star, of order 10 km [37]. This involves a breathtaking extrapolation of 18 orders of magnitude in size, or 55 orders of magnitude in mass. Nevertheless, both in the laboratory and in astrophysics, *it is the same neutrons, the same strong interactions, the same neutron rich matter, and the same equation of state.* A measurement in one domain, be it astrophysics or in the laboratory, can have important implications in the other domain. This is the real strength of a multi-messenger approach to neutron rich matter.

3.1 Neutron star radii

The structure of a neutron star can be calculated with the Tolman-Oppenheimer-Volkoff Equations of General Relativity [38] and is completely determined by the equation of state of neutron rich matter. The radius of a neutron star depends on the pressure of neutron matter at normal nuclear density and above, because the central density of a neutron star can be a few or more times

that of normal nuclear density. A higher pressure will lead to a larger radius. It is important to have both low density information on the equation of state from PREX, and high density information from measurements of neutron star radii. This can constrain any possible density dependence of the equation of state from an interesting phase transition to a possible high density exotic phase such as quark matter, strange matter, or a color superconductor. For example, if the ²⁰⁸Pb radius is relatively large, this shows the EOS is stiff at low density (has a high pressure). If at the same time, neutron stars have relatively small radii, than the high density EOS is soft with a low pressure. This softening of the EOS with density could strongly suggest a phase transition to a soft high density exotic phase.

The radius of a neutron star r_{NS} can be deduced from X-ray measurements of luminosity L and surface temperature T,

$$L = 4\pi r_{NS}^2 \sigma_{SB} T^4, \tag{3.1}$$

with σ_{SB} the Stefan Boltzmann constant. This allows one to deduce the surface area of a neutron star. However, there are important complications. First, one needs an accurate distance to the neutron star. Second, Eq. 3.1 assumes a black-body and there are important non-blackbody corrections that must be determined from models of neutron star atmospheres. Finally, gravity is so strong that space near a neutron star is strongly curved. If one looks at the front of a neutron star, one will also see about 30% of the back, because of the curvature of space. Therefore the surface area that one observes in Eq. 3.1 depends on the curvature of space and the mass of the star. Thus what started out as a measurement of just the radius is, in fact, a measurement of a combination of mass and radius.

Recently Steiner, Lattimer, and Brown have deduced masses and radii [39] from combined observations of six neutron stars in two classes: 1) X-ray bursts, and 2) neutron stars in globular clusters. They conclude that observations favor a stiff high density equation of state that can support neutron stars with a maximum mass near $2 M_{\odot}$ and that the equation of state is soft at low densities so that a 1.4 M_{\odot} neutron star has a radius near 12 km. They go on to predict that the neutron minus proton root mean square radius in ²⁰⁸Pb will be $R_n - R_p = 0.15 \pm 0.02$ fm. Note that this is a prediction for a nucleus based on an equation of state deduced from X-ray observations of neutron stars. The Steiner et al. paper [39] is potentially controversial because their results depend on, among other things, the model assumed for X-ray bursts. Ozel et al. use a different model for X-ray bursts, and get very small neutron star radii near 10 km or below [40]. The high density EOS that Ozel et al. deduce from these observations is significantly softer than Steiner et al's, suggesting a phase transition to an exotic phase [41]. Thus, the difference between Ozel et al's result of 10 km, that likely implies a phase transition, and Steiner et al's result of 12 km, that does not suggest a phase transition, is very significant. Clearly these observations of neutron star radii have potentially very important implications for the properties of neutron rich matter and the high density phases of QCD.

3.2 Solid neutron rich matter and neutron star crust cooling

We go on to discuss the neutron star crust and crust cooling. The neutron radius of ²⁰⁸Pb has implications for neutron star structure, in addition to the star's radius. Neutron stars have solid crusts over liquid cores, while a heavy nucleus is expected to have a neutron rich skin. Neutron

star crust consists of a relativistic fermi gas of electrons, a crystal lattice of neutron rich ions, and, in general, a neutron gas. For a review see [42]. Both the solid crust of the star, and the skin of the nucleus, are made of neutron rich matter at similar, slightly subnuclear, densities. The common unknown is the equation of state of neutron matter. A thick neutron skin in ²⁰⁸Pb, means a high pressure where the energy rises rapidly with density. This quickly favors the transition to a uniform liquid phase. Therefore, we find a strong correlation between the neutron skin thickness, measured by PREX, and the transition density in neutron stars from solid crust to liquid interior [28].

Perhaps the presence of a solid crust deserves comment. We expect solids to form in compact stars, both white dwarfs and neutron stars. This may sound surprising since stars are often composed of not liquids or gasses, but plasmas. Nevertheless, the plasmas can be so dense that the ions actually freeze. Recently, there are significant new observations of how white dwarfs freeze [43] and of how the solid crust of accreting neutron stars cools [44, 45, 46]. In addition, crystalization has been observed in complex laboratory plasmas, see for example [47, 48]. We hope to extract important new information, on the structure of solids in stars, by comparing these observations to large scale molecular dynamics simulations of freezing in both white dwarfs [49] and neutron stars [50].

4. Gravitational Waves

We turn now to gravitational wave observations of neutron rich matter. Albert Einstein, almost 100 years ago, predicted the oscillation of space and time known as gravitational waves (GW). Within a few years, with the operation of Advanced LIGO [51], Advanced VIRGO [52] and other sensitive interferometers, we anticipate the historic detection of GW. This will be a remarkable achievement and open a new window on the universe and on neutron rich matter.

The first GW that are detected will likely come from the merger of two neutron stars. The rate of such mergers can be estimated from known binary systems [53]. During a merger the GW signal has a so called chirp form where the frequency rises as the two neutron stars spiral closer together. Deviations of this wave form from that expected for two point masses may allow one to deduce the equation of state of neutron rich matter and measure the radius of a neutron star r_{NS} [54]. Alternatively one may be able to observe the frequency of oscillations of the hyper-massive neutron star just before it collapses to a black hole. This frequency depends on the radius of the maximum mass neutron star [55]. However, either approach may require high signal to noise data from relatively nearby mergers. Note that this information on r_{NS} from GW is independent of the X-ray observations discussed in Sec. 3 and of any systematic errors associated with the modeling of X-ray bursts.

Continuous GW signals can also be detected, see for example [56]. Indeed Bildstein and others [57] have speculated that some neutron stars in binary systems may radiate angular momentum in continuous GW at the same rate that angular momentum is gained from accretion. This would explain why the fastest observed neutron stars are only spinning at about half of the breakup rate. There are several very active ongoing and near future searches for continuous gravitational waves at LIGO, VIRGO and other detectors, see for example [58]. No signal has yet been detected. However, sensitive upper limits have been set. These limits constrain the shape of neutron stars. In some cases the star's elipticity ε , which is that fractional difference in moments of inertia ε =

 $(I_1 - I_2)/I_3$ is observed to be less than a part per million or even smaller. Here I_1 , I_2 , and I_3 are the principle moments of inertia.

In general, the amplitude of any continuous signal is much weaker than a burst signal. However, one can gain sensitivity to a continuous signal by coherently (or semi-coherently) integrating over a large observation time, see for example [59]. Note that searches for continuous GW can be very computationally intensive because one must search over an extremely large space of parameters that may include the source frequency, how that frequency changes with time, the source location on the sky, etc. The Einstein at home distributed computing project uses spare cycles on the computers of a large number of volunteers to search for continuous GW [60].

Strong GW sources often involve large accelerations of large amounts of neutron rich matter. Indeed the requirements for a strong source of continuous GW, at LIGO frequencies, places extraordinary demands on neutron rich matter. Generating GW sounds easy. Place a mass on a stick and shake vigorously. However to have a detectable source, one may need not only a large mass, but also a very strong stick. The stick is needed to help produce large accelerations. Since others have discussed large masses, let us focus here on the strong stick.

An asymmetric mass on a rapidly rotating neutron star produces a time dependent mass quadrupole moment that radiates gravitational waves. However, one needs a way (strong stick) to hold the mass up. Magnetic fields can support mountains, see for example [61]. However, it may require large internal magnetic fields. Furthermore, if a star also has a large external dipole field, electromagnetic radiation may rapidly spin the star down and reduce the GW radiation.

Alternatively, mountains can be supported by the solid neutron star crust. Recently we performed large scale MD simulations of the strength of neutron star crust [62, 63]. A strong crust can support large deformations or "mountains" on neutron stars, see also [64], that will radiate strong GW. How large can a neutron star mountain be before it collapses under the extreme gravity? This depends on the strength of the crust. We performed large scale MD simulations of crust breaking, where a sample was strained by moving top and bottom layers of frozen ions in opposite directions [62]. These simulations involve up to 12 million ions and explore the effects of defects, impurities, and grain boundaries on the breaking stress.

We find that neutron star crust is very strong because the high pressure prevents the formation of voids or fractures and because the long range coulomb interactions insure many redundant "bounds" between planes of ions. Neutron star crust is the strongest material known, according to our simulations. The breaking stress is 10 billion times larger than that for steel. This is very promising for GW searches because it shows that large mountains are possible, and these could produce detectable signals.

Consider a surface wave on a rapidly rotating neutron star that is moving slowly in a direction opposite to the stars rotation. This wave, in the laboratory frame, will appear to be moving in the direction of the star's rotation. The back reaction force on the wave from GW radiation will always act to slow the wave in the laboratory frame. However, in this case slowing in the lab frame will actually speed up the wave in the rotating star's frame and increase its amplitude. Thus the wave can be unstable with respect to gravitational wave radiation. The r-modes are collective oscillations on rotating neutron stars that can also be unstable to GW radiation [65]. If an r-mode is unstable the amplitude will grow large and rotational kinetic energy can be radiated away as GW. This will slow

the rotation rate. Note, that the physics of large amplitude r-mode oscillations can be complicated, see for example [66, 67].

The stability of r-modes depends on the amount of dissipation from, for example, the bulk and shear viscosities of neutron rich matter. If dissipation is large then the amplitude of the r-modes will stay small and rapid rotation of a neutron star is possible. Alternatively, if dissipation is small then the r-modes may be unstable and GW radiation from the modes may limit the rotation rate of the star. Unfortunately the stability of r-modes has proved to be a complex subject that may be sensitive to subtle dissipation properties of neutron rich matter, be it in a nucleon phase [68, 69] or in more exotic quark and gluon phases [70, 71, 72].

We give one example of a possible source of dissipation for the r-modes. The shear viscosity of conventional complex fluids, with large non-spherical molecules, can be orders of magnitude larger than that for normal fluids. This suggests that the shear viscosity of nuclear pasta, with long rod like shapes as seen in Fig. 1, could be large. In ref. [73], we have calculated the shear viscosity of nuclear pasta using large scale molecular dynamics simulations. The shear viscosity is dominated by momentum carried by electrons and although the electron mean free path is determined by electron-pasta scattering, we find no dramatic differences from a conventional phase with spherical nuclei. Therefore, we find that the shear viscosity of nuclear pasta is not very different from that for more conventional matter with nearly spherical nuclei. However there could be other sources of dissipation. We do not yet have a complete understanding of when the r-modes may be stable and when they are unstable.

To conclude this section, there is a great deal of interest in gravitational waves (GW) from neutron stars and there are many ongoing searches. One is interested in both burst sources, for example from neutron star mergers, and continuous sources from mountains or collective modes. Gravitational wave radiation depends on the equation of state of neutron rich matter. In addition, it can also depend on other more detailed properties including the breaking strain of solid phases and the bulk and shear viscosities.

5. Supernova neutrinos and neutron rich matter

Neutrinos provide yet another, qualitatively different, probe of neutron rich matter. Core collapse supernovae (SN) are gigantic stellar explosions that convert as much as $0.2M_{\odot}$ of mass into 10^{58} neutrinos [74]. We detected about 20 neutrinos from SN1987a [75, 76]. The next galactic SN should be very exciting. There are many new underground experiments to search for dark matter, double beta decay, solar neutrinos, proton decay, oscillation of accelerator neutrinos, etc. Some of these experiments can be very sensitive to SN neutrinos. For example, the coming ton scale dark matter experiments can be sensitive to SN neutrinos via neutrino-nucleus elastic scattering [77].

In a SN, neutrinos are emitted from the surface of last scattering known as the neutrino-sphere. At the neutrino-sphere, the neutrino mean free path is comparable to the size of the system. The temperature is of order 4 MeV, based on the energies of the SN1987a events. The density is $\approx 10^{11}$ g/cm³, 1/1000 to 1/100 of normal nuclear density. This follows from the mean free path implied by known neutrino cross sections. Thus, the neutrino-sphere is a low density warm gas of neutron rich matter. The pressure, composition, and long wave-length neutrino response [78] of this region can be calculated from a model independent Virial expansion [79, 80]. This expansion is based on

nucleon-nucleon, nucleon-alpha, and alpha-alpha elastic scattering phase shifts. Neutrino-sphere conditions can be simulated in the laboratory with heavy ion (HI) collisions. For example during a peripheral collision, fragments emitted with velocities intermediate between those of the projectile and target are coming from a warm low density region, see for example [81].

The next galactic SN should provide a great deal of information on neutrino properties such as oscillations, masses, and mixing angles. We give one example of an important SN neutrino observable related to nucleosynthesis. About half of the elements heavier than 56 Fe, including gold and uranium, are thought to be made in the r-process of rapid neutron capture nucleosynthesis [83]. Here seed nuclei rapidly capture many neutrons to produce very neutron rich nuclei that then beta decay several times to produce heavy elements such as gold. At this time, the preferred site for the r-process is the neutrino driven wind during a supernova, see for example [84]. Here some baryons are blown off of the proto-neutron star by the intense neutrino flux. Nucleosynthesis in this wind depends on the entropy, the expansion time scale, and most importantly the proton fraction Y_p (number of protons divided by the total number of protons and neutrons). The proton fraction is set by the relative rates of neutrino and antineutrino capture.

$$V_e + n \to p + e \tag{5.1}$$

$$\bar{\mathbf{v}}_e + p \to n + e^+ \tag{5.2}$$

The cross sections for these reactions depend on neutrino and antineutrino energies. Therefore one should measure the difference ΔE between the average energy of electron antineutrinos and neutrinos,

$$\Delta E = \langle E_{\bar{\nu}_a} \rangle - \langle E_{\nu_a} \rangle. \tag{5.3}$$

If ΔE is large, the wind can be neutron rich. However if ΔE is small, the wind will be proton rich and this is likely a serious problem for r-process nucleosynthesis in the wind [85]. The wind has been the preferred r-process site because, for example, it is a known explosive environment that occurs relatively often so it can easily supply enough r-process material. However, present simulations of the wind do not have a large enough ratio of free neutrons to seed nuclei. One can increase this ratio by lowering Y_p (and increasing the number of neutrons) or by increasing the entropy (and destroying some of the seed nuclei).

A proton in neutron rich matter is more tightly bound than a neutron. This is because of the symmetry energy and this binding energy difference can increase the cross section for Eq. 5.1 and decrease the cross section for Eq. 5.2, [82]. This could change the Y_p in the neutrino driven wind and impact nucleosynthesis.

Finally, calculations of r-process nucleosynthesis yields also require important nuclear structure input including masses of neutron rich nuclei, beta decay half lives, and neutron capture cross sections [83]. New radioactive beam accelerators, such as FRIB, can directly produce some of the neutron rich nuclei involved in the r-process and provide important nuclear structure data. However this nuclear data may not, by itself, directly address important astrophysical questions involving the site of the r-process and the source of the neutrons.

In any case, measuring ΔE , during the next galactic SN, should provide an important diagnostic on conditions in the neutrino driven wind. At present the site of the r-process is unknown [86]. One alternative site for the r-process is tidally ejected material during neutron star mergers, see for

example [87][88][89]. If this is the site, there may be an observable electromagnetic signal associated with the radioactive decay of r-process nuclei, see for example [90]. The Spaniards started a quest to find the city of Eldorado. Perhaps with SN neutrinos or electromagnetic observations of neutron star mergers, we can end this quest and find the source of the chemical element gold.

6. Conclusions: neutron rich matter

Neutron rich matter is at the heart of many fundamental questions in Nuclear Physics and Astrophysics. What are the high density phases of QCD? Where did the chemical elements come from? What is the structure of many compact and energetic objects in the heavens, and what determines their electromagnetic, neutrino, and gravitational-wave radiations? Moreover, neutron rich matter is being studied with an extraordinary variety of new tools such as the Facility for Rare Isotope Beams (FRIB) and the Laser Interferometer Gravitational Wave Observatory (LIGO).

We described the Lead Radius Experiment (PREX) that uses parity violating electron scattering to measure the neutron radius in ²⁰⁸Pb. This has important implications for neutron stars and their crusts. We discussed X-ray observations of neutron star radii that also have important implications for neutron rich matter. Gravitational waves (GW) from sources such as neutron star mergers and rotating neutron star mountains open a new window on neutron rich matter. Using large scale molecular dynamics simulations, we found neutron star crust to be the strongest material known, some 10 billion times stronger than steel. It can support mountains on rotating neutron stars large enough to generate detectable gravitational waves. Finally, neutrinos from core collapse supernovae (SN) provide another, qualitatively different probe of neutron rich matter. Neutrinos come from the neutrino-sphere that is a low density warm gas phase of neutron rich matter. Neutrinosphere conditions can be simulated in the laboratory with heavy ion collisions. Observations of neutrinos can probe nucleosyntheses in SN while SN simulations depend on the equation of state (EOS) of neutron rich matter.

In conclusion, multi-messenger astronomy is based on the widely held belief that combining astronomical observations using photons, gravitational waves, and neutrinos will fundamentally advance our knowledge of compact and energetic objects in the heavens. Compact objects such as neutron stars are, in fact, giant nuclei, even if they are an extraordinary 18 orders of magnitude larger than a ²⁰⁸Pb nucleus. Nevertheless, both in the laboratory and in Astrophysics, these objects are made of the same neutrons, that undergo the same strong interactions, and have the same equation of state. A measurement in one domain, be it Astrophysics or the laboratory, can have important implications in the other domain. Therefore we can generalize multi-messenger astronomy to multi-messenger observations of neutron rich matter. We believe that combing astronomical observations using photons, GW, and neutrinos, with laboratory experiments on nuclei, heavy ion collisions, and radioactive beams will fundamentally advance our knowledge of the heavens, the dense phases of QCD, the origin of the elements, and of neutron rich matter.

Acknowledgments

This work was done in collaboration with many people including D. K. Berry, E. F. Brown, K. Kadau, J. Piekarewicz, and graduate students Liliana Caballero, Helber Dusan, Joe Hughto,

Justin Mason, Andre Schneider and Gang Shen. This work was supported in part by DOE grant DE-FG02-87ER40365 and by the National Science Foundation, XSEDE grant TG-AST100014.
