E-mail: B.K.Gjelsten@fys.uio.no

Searches for physics beyond the Standard Model of particle physics are about to enter a new era with the startup of the Large Hadron Collider (LHC) at CERN. Prospects for R-parity conserving supersymmetry discovery and measurements with the ATLAS detector at the LHC are presented. Methods for determining the parameters of the underlying supersymmetry model and the relation to dark matter estimation are discussed.

Identification of dark matter 2008

August 18-22, 2008

Stockholm, Sweden

*Speaker.

†On behalf of the ATLAS collaboration.

1. Introduction

A long standing problem of fundamental physics regards the status and features of dark matter, a kind of matter not accounted for in the Standard Model (SM) of particle physics but needed to explain various cases in astronomy and cosmology like the observed rotation of galaxies. In later years dark matter predictions have been brought to very high precision with the measurement of anisotropies in the cosmic microwave background [1].

One of the most promising candidates for a theory beyond the Standard Model which also provides a viable candidate for dark matter is R-parity conserving supersymmetry (SUSY). In these models the spectrum of elementary particles is extended to include supersymmetric partners which differ from their Standard Model counterparts by half a unit of spin. Accompanying the quarks, leptons, gluons, gauge bosons and higgses (of the extended Higgs sector) there will be squarks, sleptons, gluinos, gauginos and higgsinos, respectively. The two latter types have overlapping quantum numbers and mix to give charginos and neutralinos mass eigenstates.

To comply with experimental non-observation (no spin-0 electron has ever been observed) the sparticles must be heavier than the Standard Model particles: supersymmetry must be broken. Our ignorance of the origin of supersymmetry breaking introduces >100 free parameters (masses, mixing angles, phases) into the low-energy Lagrangian. Some of the new couplings give rapid proton decay unless considerably constrained. The addition of a new, conserved symmetry, R-parity, removes all such dangerous terms. The introduction of R-parity has the important side effect that any interaction must involve an even number of superpartners. This means that there will be a Lightest Supersymmetric Particle (LSP) which is stable and hence a candidate for dark matter. In most relevant cases, and assumed in this paper, the lightest neutralino ($\tilde{\chi}_1^0$) will be the LSP.

The Minimal Supersymmetric Model (MSSM), which is the minimal implementation of supersymmetry onto the Standard Model with no additional assumptions except R-parity conservation, contains 105 undetermined parameters. To avoid Flavour-Changing Neutral Currents (FCNC) and CP violation beyond experimental values, assumptions on the many free parameters are usually made, effectively reducing the dimension of parameter space to handleable proportions, and also rendering the models more apt for phenomenological studies. So-called Minimal Supergravity (mSUGRA), contains only four continuous parameters, all given at the GUT scale: m_0 and $m_{1/2}$, the masses of the spin-0 and the spin-1/2 sparticles, respectively, A_0 , the trilinear coupling, $\tan\beta$, the vacuum-expectation value (VEV) of the neutral component of the Higgs doublet giving masses to up-type particles divided by the VEV of the neutral component of the Higgs doublet giving masses to down-type particles, as well as the sign of the Higgs potential parameter μ . The investigations reported on in this write-up are conducted within mSUGRA unless otherwise specified.

Despite decades of searches at the major experimental sites there is yet no evidence that nature is supersymmetric. Instead limits are set, mainly by the non-observation at LEP and Tevatron. With the startup of the Large Hadron Collider (LHC) a new energy regime will be explored. While the Tevatron has $p\bar{p}$ collisions at 2 TeV center of mass energies, the LHC is constructed to collide protons on protons at 14 TeV. The relevant center of mass energy is however that of the colliding quarks/antiquarks/gluons, constituents of the proton, yielding an effective center of mass energy of the order of a few TeV. Nevertheless, if supersymmetry is to address the hierarchy problem, as

is one of its main motivations, supersymmetric particles should have masses not very much above 1 TeV, and hence in most cases be accessible by the effective center-of-mass energies of the LHC.

2. Inclusive searches

With R-parity conserved, sparticles will be produced in pairs at colliders. If not too heavy, squarks and gluinos will dominate the SUSY production at LHC due to the strong interactions. Each of the initial sparticles will then set off a cascade of decays into lighter and lighter sparticles, at each step splitting off Standard Model particles; gluons, quarks and leptons as well as W's, Z's, Higgses and photons. The LSP, neutral and weakly interacting, will leave the detector without a trace, but not traceless. While each hard-collision in a hadron-hadron machine will have a varying, non-zero boost in the beam direction leaving this variable insensitive to the non-detected LSPs, the momenta in the transverse direction should sum up to zero. The transverse energy carried away by the two escaping LSPs produces the most generic signature of R-parity conserving SUSY: missing transverse energy (E_T^{miss}). Additional signatures are several hard jets and possibly leptons, both produced directly in the cascade or in the decay of intermediate W, Z or Higgs bosons. (Hard photons are crucial in SUSY models where the breaking is mediated by gauge interactions, not considered in this paper.) Natural SUSY search channels are therefore based on considerable E_T^{miss} , N hard jets and M leptons. A simple variable incorporating all of these features and therefore apt to distinguish SUSY from SM events is the effective mass (M_{eff}), defined as the scalar sum of E_T^{miss} and the transverse momentum of each of the jets and leptons.

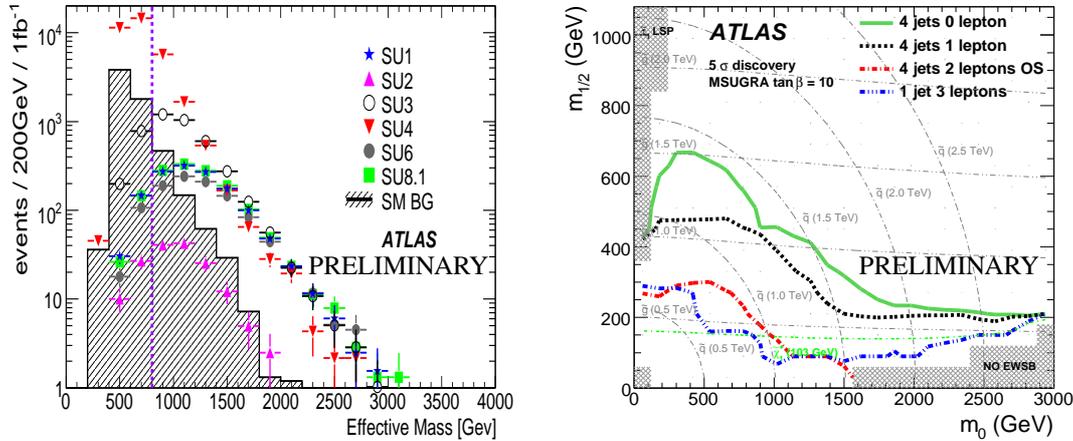

Figure 1: Left: M_{eff} distribution for mSUGRA benchmark scenarios SU_x and SM in the 0-lepton 4-jet channel. See [2] for definition of the SU_x scenarios. SUSY signal is visible over SM for most scenarios. Right: 5-sigma mSUGRA discovery contours. Both plots correspond to 1 fb^{-1} of integrated luminosity.

Figure 1 (left) shows M_{eff} for a set of mSUGRA benchmark points in the 0-lepton 4-jet channel. Most of the benchmark scenarios show a noticeable excess of events at high M_{eff} values already with 1 fb^{-1} , which is of the order of the integrated luminosity expected to be collected in 2009–2010. The right plot shows expected 5-sigma discovery contours with 1 fb^{-1} of ATLAS data for mSUGRA in m_0 and $m_{1/2}$ with $\tan \beta = 10$, $A_0 = 0$ and $\mu > 0$ fixed. Selection cuts are detailed in [2],

where also many other search channels are discussed. If nature is supersymmetric with a realisation giving phenomenologies not too different from mSUGRA (in particular in E_T^{miss} and jet hardness), and the SUSY scale is such that the hierarchy problem is addressed, then ATLAS is likely to make discoveries already with 1 fb^{-1} which might be reached in the first years of operation.

3. SUSY dark matter

To confirm that an excess above the SM, as could be observed e.g. in the M_{eff} distribution, Figure 1 (left), is in fact due to SUSY, exclusive studies would be needed in which particular decay chains are sought isolated. This is also what is needed in order to estimate the supersymmetric contribution to dark matter. In the very early universe the LSPs would be in thermal equilibrium, $\tilde{\chi}_1^0 \tilde{\chi}_1^0 \rightleftharpoons f \bar{f}$. As the universe expanded and the temperature eventually sank below the LSP mass, annihilation of LSPs would start to dominate over their production. Then, at some stage, with the steady reduction of the LSP density, the collision rate would effectively come to a stop. This is the moment of LSP freeze-out. The amount of LSP relic density of the universe today is determined by the efficiency of the LSP annihilation before freeze-out, i.e. by the cross section for $\tilde{\chi}_1^0 \tilde{\chi}_1^0 \rightarrow f \bar{f} / W^+ W^- / ZZ$ (and also for co-annihilation, e.g. $\tilde{\chi}_1^0 \tilde{\tau} \rightarrow \tau \gamma$).

In order to determine the LSP relic density from ATLAS data, it is therefore critical to estimate the SUSY parameters which enter the dominating annihilation process(es). In different parts of SUSY parameter space, different annihilation processes are dominating. In mSUGRA the LSP (the lightest neutralino, $\tilde{\chi}_1^0$) is usually mostly bino, i.e. the partner of the U(1) gauge boson. In this case the basic annihilation process $\tilde{\chi}_1^0 \tilde{\chi}_1^0 \rightarrow f \bar{f}$ through the exchange of a slepton (or squark) usually has too low cross section. Unless the LSP and slepton (squark) masses are sufficiently low (bulk region), this annihilation process will not alone be enough to reduce the LSP density to the required amounts before freeze-out, resulting in too large relic density, already excluded by current dark matter estimates. This situation also ports into non-mSUGRA models. One way to increase the annihilation rate, is to have the bino-content of the LSP diluted by wino (SU(2) coupling) and/or higgsino components. In mSUGRA scenarios only the latter possibility is allowed (focus point region). Outside of mSUGRA both possibilities can occur with ease. Another way in which the annihilation cross section will be enhanced is through resonant s-channel scattering with an intermediate Higgs boson. For this to happen $m_{h/H/A} \approx 2m_{\tilde{\chi}_1^0}$ must be satisfied (Higgs funnel region). Yet another way is if the next-to-lightest sparticle(s) (NLSP) is not much heavier than the LSP. Then co-annihilation of LSP+NLSP assists in reducing the LSP density to the required amounts.

Some of the most relevant quantities to measure (or control) are therefore the mass of the LSP, of the (lightest) sleptons/squarks (and whether they are superpartners of left-handed or right-handed SM particles), the neutral Higgs masses. Furthermore, to determine the LSP composition the mass of additional neutralinos are important.

4. Endpoints

Reconstructing SUSY events from the measured quantities, jets, leptons and E_T^{miss} is complicated by the undetected LSPs (and the measured E_T^{miss} cannot easily be split between them) as well

as there being two decay chains. The latter adds combinatorial background, the former requires the use of endpoints rather than mass peaks to determine masses.

In large parts of SUSY parameter space the next-to-lightest neutralino ($\tilde{\chi}_2^0$) is lighter than the initially produced squarks (and gluinos). This allows for the golden decay chain $\tilde{q} \rightarrow q\tilde{\chi}_2^0 (\rightarrow q\ell\tilde{\ell}) \rightarrow q\ell\ell\tilde{\chi}_1^0$ which is particularly useful when ℓ denotes electrons or muons, since these are very accurately reconstructed in ATLAS. (The parenthesis is opened if $m_{\tilde{\chi}_2^0} > m_{\tilde{\ell}}$. If $m_{\tilde{g}} > m_{\tilde{q}}$, an additional jet may come into useful play from an initial $\tilde{g} \rightarrow q\tilde{q}$.) With such a chain isolated, four invariant masses can be constructed from the three available four-vectors, $m_{\ell\ell}$, $m_{\ell\ell q}$ and two copies of $m_{\ell q}$ (which can be kept apart). Add more events, and four distributions are obtained. While the peaks of these distribution have no significant interpretation, the endpoints do, and are given by simple formulas involving the masses of the intermediate sparticles. With sufficient endpoints measured the relevant sparticle masses can be determined.

Similar techniques can be used on the decay $\tilde{g} \rightarrow t\tilde{t}_1 \rightarrow tb\tilde{\chi}_1^\pm$ to constrain the mass of the lighter stop, which if sufficiently light would add an important co-annihilation processes. The stau mass(es) can be constrained by $\tilde{\chi}_2^0 \rightarrow \tau\tilde{\tau} \rightarrow \tau\tau\tilde{\chi}_1^0$ if open, although with precision much inferior to the selectron/smuon case. For sleptons with mass above $\tilde{\chi}_2^0$, mass constraints might be obtained from an M_{T2} (see [2]) analysis of direct slepton production $\tilde{\ell}\tilde{\ell} \rightarrow \ell\ell\tilde{\chi}_1^0\tilde{\chi}_1^0$. Similar techniques may be used to obtain the mass of the right-handed squark (\tilde{q}_R). Comparison of branching ratios is another instrument to obtain information on quantities of relevance to LSP relic density estimates.

Some of these measurements will need many years of LHC operation, others can be made the first year, although with limited precision.

5. “First year” luminosity, 1.0 fb^{-1}

For the mSUGRA benchmark point SU3 the golden decay chain will give important information already at 1 fb^{-1} . Figure 2 shows two of the available mass distributions.

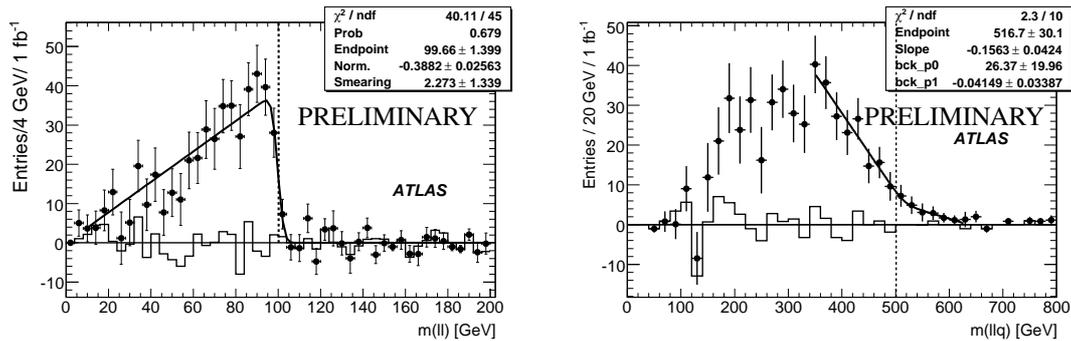

Figure 2: Distributions of $m_{\ell\ell}$ and $m_{\ell\ell q}$ for benchmark point SU3 at 1 fb^{-1} integrated luminosity. (Bins of negative value occur from a subtraction technique where events of opposite-flavour are subtracted from the same-flavour ones, which effectively removes large parts of the background.) The vertical lines mark the theoretical endpoints. The distributions fall off close to the theoretical endpoint.

The edges are clear and can be fitted with appropriate functions, although more luminosity will clearly improve the precision. The two $m_{\ell\ell q}$ distributions as well as an additional $m_{\ell\ell q}$ distribution

also give endpoint measurements, allowing the masses to be determined although at quite low precision. Some other SU3 measurements which can be made at 1 fb^{-1} are the $m_{\tau\tau}$ endpoint, the mass of the right-handed squark as well as an endpoint involving the lighter stop, see [2] for details.

Combining the endpoints of the golden chain with the $m_{\tilde{q}_R}$ measurement, an mSUGRA scan can be performed to constrain the SUSY parameters. Table 1 shows the result. The mass parameters m_0 and $m_{1/2}$ are already accurately determined, with 9% and 2% uncertainty, respectively, and the sign of μ is correctly found. The two other parameters, $\tan\beta$ and in particular A_0 are however not very well constrained by the 1 fb^{-1} measurements.

Table 1: Nominal and estimated mSUGRA parameters for SU3 at 1 fb^{-1} .

Parameter	SU3 value	fitted value	exp. unc.
$\tan\beta$	6	7.4	4.6
m_0	100 GeV	98.5 GeV	$\pm 9.3 \text{ GeV}$
$m_{1/2}$	300 GeV	317.7 GeV	$\pm 6.9 \text{ GeV}$
A_0	-300 GeV	445 GeV	$\pm 408 \text{ GeV}$

The final step, estimation of the relic density, is not made in this study. While it seems plausible that the relic density under the assumption of mSUGRA could be determined with sufficient precision that a comparison with WMAP values would make sense, going outside of mSUGRA probably will require considerably higher integrated luminosities.

6. “Ultimate” luminosity, 300 fb^{-1}

In [3] the LSP relic density of the mSUGRA benchmark point SPS 1a, quite similar to the SU3 point studied above, is estimated from ATLAS measurements after an “ultimate” integrated luminosity of 300 fb^{-1} . In this study an mSUGRA scenario is assumed from the start, and a top-down approach is taken, i.e. simply scanning over the SUSY parameters. With the high precision on the ATLAS measurements after 300 fb^{-1} , the mSUGRA parameters are well determined, $\sigma(m_0)/m_0 = 2\%$, $\sigma(m_{1/2})/m_{1/2} = 0.6\%$, $\sigma(\tan\beta)/\tan\beta = 9\%$, $\sigma(A_0)/A_0 = 16\%$, yielding a precision on the LSP relic density of $\sim 3\%$.

While such a scan will undoubtedly be performed should ATLAS provide the relevant measurements, it would be unwise to rely too much on nature having settled on such a well-behaving model. Non-consistency with mSUGRA assumptions would be revealed by bad likelihood values of the parameter fit, provided the measurements come with sufficient precision. Less constrained models would then need to be considered.

In [4] the same objective is undertaken for a similar benchmark point, SPS 1a', and the same integrated luminosity, but with the mSUGRA assumptions relaxed to 24-parameter MSSM. A bottom-up approach is attempted in which each sparticle sector is reconstructed as much as the measurements allow, then the remaining degrees of freedom are scanned over to monitor the sensitivity of the relic density to the undetermined parameters. The neutralino sector is attacked first. The masses of $\tilde{\chi}_1^0$ and $\tilde{\chi}_2^0$, determined from the endpoints, provide two constraints on the four parameters defining the sector. For SPS 1a' also the mass of $\tilde{\chi}_4^0$ can be determined, leaving only one

parameter unconstrained, here taken as $\tan\beta$. Next, the slepton sector is attacked, which turns out somewhat more involved. Out of several unsettled issues the largest effect on the relic density is however found to come from the uncertainty with which the mass of the lightest stau can be determined (i.e. the uncertainty on the endpoint $m_{\tau\tau}$). Finally the Higgs sector is investigated, mainly to assess the possibility of LSP annihilation through Higgs resonance. The final precision on the relic density is found to be 20%(10%) for $\sigma(m_{\tau\tau}) = 5(1)$ GeV. The results are less precise than the mSUGRA precision of 3%, but nevertheless impressive. A top-down analysis for 24-parameter MSSM on the same SPS 1a' measurements confirms the results[5].

7. Summary

If supersymmetry is to have a word on the hierarchy problem, and is realised with phenomenologies (in particular in the amount of E_T^{miss} and jet hardness) comparable to the mSUGRA models widely studied, ATLAS has good opportunities of making discoveries in the early phases of operation. For favourable scenarios measurements of exclusive quantities can be made with moderate precision already in the first year, and with very high precision after some years. For less favourable scenarios more luminosity is needed to start characterising the specific instance of supersymmetry. The accuracy with which the LSP relic density can be estimated, depends quite a lot on our location in SUSY parameter space. With ultimate luminosity an accuracy of 10% can be achieved in very favourable cases. In other cases very little can be claimed. There is however an interesting asymmetry in the problem. If, from ATLAS measurements, one of the annihilation processes is found to reduce the relic density below the measured dark matter density, we would already know, regardless of the status of the other annihilation processes, that SUSY alone does not account for all the dark matter. Also, if one of the processes is found to give LSP relic density in good agreement with the current dark matter limits (with the cross section of the other processes remaining unknown), temptation will be large to discard the possibility of this being accidental, and hence suggest that the (principal) dark matter content of the universe is indeed supersymmetric. A final word on supersymmetry at colliders and dark matter: stability of the LSP at ATLAS time scales, as testified by large amounts of E_T^{miss} does not guarantee LSP stability at the time scale of the universe.
