The Crab Nebula in the infrared: a review

Figure 1: Composite image of the Crab Nebula obtained with the Chandra X-ray image (blue), Hubble telescope optical image (green), and the Spitzer infrared image (red).

1. Introduction

The Crab Nebula is one of the brightest synchrotron source in the Galaxy. It is a prototype of a class of SNRs called plerions, which are powered by a central pulsar. The supernova which produced the Crab Nebula is located in the constellation of Taurus at a distance of about 2 kpc.

Comparing the X-ray, optical and infrared images obtained respectively with Chandra, Hubble Space Telescope and the Spitzer Space telescope (see the composite image of Figure 1), results that the nebula appears most compact in X-rays and largest in the infrared. This can be understood by the fact that ultrahigh-energy X-ray emitting electrons radiate away their energy more quickly than the lower-energy electrons emitting optical and infrared radiation.

One of the main reasons to observe the Crab Nebula in the infrared is to test the hypothesis that part of the interstellar dust does originate from SNe. In fact the infrared (IR) is an ideal spectral region in which to test these theories because dust grains emit strongly in the IR. In addition the comparison of the spectral index derived from IR observations with those obtained in the radio and UV-Opt. spectral regions, is foundamental in understanding the physical mechanisms of emission in the Crab Nebula.

In Sect.2 will be presented a review of the main infrared observations of the Crab Nebula,

while in Sect.3 are reported the recent Spitzer images. Polarimetric infrared observations are briefly described in Sect.4, and in Sect.5 a summary is reported.

2. Infrared observations

2.1 Near-Infrared

Near-infrared photometric observations of the Crab Nebula were obtained in the past by different authors (see i.e. [1], [2]). From the dereddened spectral energy distribution obtained combining the observed integrated flux densities from 1-5 µm with optical data, a spectral index of $\alpha = -0.46$ ($f_\nu \propto \nu^{-\alpha}$) was derived ([2]) . This value supports the synchrotron mechanism in the near-IR. In addition, the first image at 2.2 µm obtained by [2] showed a strict correlation with the visible flux distribution.

With the advent of the near-IR array detectors has been possible to study in details the morphology of the nebula and the central pulsar. Particularly interesting are the 1.644 µm images centered on the [Fe II] line obtained by [3] and [4] (left panel of Fig.2). These images are dominated by a prominent filament structure identical to the [Ni II] image indicating that the gas phase distribution of Fe$^+$ and Ni$^+$ are very similar. In two of the filaments, [6] report the discovery of H$_2$ emission at 2.122 µm . This discovery raises fascinating questions about the origin, survival, and excitation of the molecular gas in the Crab Nebula. New high resolution images centered on the H$_2$ line and nearby continuum, have been recently obtained at the Telescopio Nazionale Galileo (TNG) using the NICS camera in order to detect hydrogen emission knots in the central part of the Crab. The results of these observations will be presented in a forthcoming paper.

Sub-arcsec resolution image in the continuum at 2.2 µm ([5]) shows the presence of bright and faint equatorial wisps and a polar knot (right panel of Fig.2) around the central pulsar. These

2.2 Mid and Far-Infrared

The Crab Nebula was observed between 12 and 100 µm with IRAS ([7]). The observations show an infrared excess beyond 12 µm over the extrapolated radio and near-IR fluxes peaking between 60 and 100 µm (left panel of Fig.3). This has been interpreted as due to thermal radiation by dust at temperature of 46 K and with mass of 0.02 M\(_{\odot}\) ([8]). Images at 60 and 100 µm taken with ISOPHOT at higher spatial resolution reveal that about half this excess is attributable to two peaks, separated by ~80 arcsec [9].

Spectro-imaging observations between 6.5 and 16.5 µm of the central 3 arcmin×3 arcmin part of the nebula at a spatial resolution of 6 arcsec were obtained with ISOCAM by [10]. Ionic lines of [Ne II], [Ne III], [Ne V] at respectively 12.8, 15.5 and 14.3 µm, of [Ar II], [Ar III] at 7.0 and 9.0 µm and of [S IV] at 10.5 µm were detected (see right panel of Fig.3).

The image centered on the [NeIII] emission shows a filamentary structure, similar to the structure seen in the optical ionic lines. These filaments are known to be composed predominately of supernova ejecta. Completely different is the morphology of the nebula in the continuum at about 11.3 µm that is similar to the synchrotron nebula seen at other wavelengths (radio, optical, X-rays). Therefore, the mid-IR emission from the Crab is dominated by synchrotron radiation; no dust is detected in this spectral region.

3. SPTZER Images

Images of the Crab Nebula at 3.6, 4.5, 5.8, 8.0, 24, and 70 µm were obtained with the Spitzer Space Telescope IRAC and MIPS cameras ([4]). Figure 4 shows the four IRAC images (panel c,d,e,and f) of the central part of the nebula. The pulsar, and the associated equatorial toroid and polar jet structures seen in Chandra and Hubble Space Telescope images (panel a, and b in Fig.4) can be identified in all of the IRAC images. The 8.0 µm image, including the [Ar II] 7.0 µm line,

Figure 4: SPITZER/IRAC images at 3.6, 4.5, 5.8 and 8.0 µm (panels c,d,e,and f respectively) of the central part of the Crab Nebula. The Chandra X-ray ACIS-S and HST optical images are reproduced for comparison in panels a and b ([4])

resembles the general morphology of visible $H\alpha$ and near-IR [Fe II] line emission, while the 3.6 and 4.5 µm images are dominated by continuum synchrotron emission.

The 24 and 70 µm images show enhanced emission that may be due to line emission or the presence of a small amount of warm dust in the nebula on the order of less than 1% of a solar mass.

4. Infrared polarimetry

Polarimetric imaging observations in different spectral regions, remain central to an understanding of the structure and evolution of the Crab Nebula. The only infrared polarimetric observations of the Crab Nebula have been obtained with the ISOCAM at 6.7 and 14.3 µm ([11]) and ISOPHOT at 25 and 170 µm ([12]). The preliminary results reported by [11] indicate that the pat-
tern of spatially coherent vectors shows some similarity to that seen in the radio and optical regimes (left panel of Fig. 5). The polarimetry at 170 µm obtained by [12] gives a preliminary polarization intensity $p=8.2\%$ with an orientation angle $\Theta=103^\circ$ at the position of the peak polarized intensity.

Further polarimetric observations in the near-IR are planned at the Italian TNG telescope in order to compare the polarimetry of the Crab Nebula in different spectral regions.

5. Summary

In this paper the main infrared observations of the Crab Nebula are discussed. From these observations, the following conclusions can be derived:

a) The near and mid-IR continuum in the Crab Nebula is dominated by synchrotron emission. Ionic lines have been observed in these spectral regions with a filamentary structure similar to that observed in the optical lines.

b) A break in the spectral energy distribution between 60 and 100 µm suggests the presence of dust at a temperature of 46K.

c) The structures observed in the optical and X-ray associated with the pulsar are also present in the near-IR until 8 µm.

d) More polarimetric observations, specially in the near-IR are requested in order to understand the mechanism of emission in the central part of the nebula.
