We report on the calculation of the next-to-leading order QCD corrections to the production of W-boson pairs in association with a hard jet at the Tevatron and the LHC, which is an important source of background for Higgs and new-physics searches. Leptonic decays of the W bosons are included by applying an improved version of the narrow-width approximation that treats the W bosons as on-shell particles, but keeps the information on the W spin. A selection of differential NLO QCD cross sections is provided both for the LHC and the Tevatron. The QCD corrections stabilize the LO prediction for the cross section with respect to scale variations. The differential LO cross sections are generally not simply rescaled by the corrections. Their shapes are particularly distorted if an additional energy scale is involved.

## 1. Introduction

The search for new-physics particles—including the Standard Model Higgs boson—will be the primary task in high-energy physics in the era of the LHC. The extremely complicated hadron collider environment does not only require sufficiently precise predictions for new-physics signals, but also for many complicated background reactions that cannot entirely be measured from data. Among such background processes, several involve three, four, or even more particles in the final state, rendering the necessary next-to-leading-order (NLO) calculations in QCD very complicated. This problem led to the creation of an “experimenters’ wishlist for NLO calculations” [1, 2, 3] that were still missing at that time, but are required for successful LHC analyses. The process  $pp \rightarrow W^+W^- + \text{jet} + X$  made it to the top of this list. Meanwhile the  $2 \rightarrow 3$  particle processes and also some of the  $2 \rightarrow 4$  particle processes [4, 5] on the list have been evaluated at NLO QCD. Moreover, benchmark results for the virtual corrections have been presented for a specific phase-space point for all  $2 \rightarrow 4$  processes on the list in Ref. [6].

The process of  $WW+\text{jet}$  production is an important source for background to the production of a Higgs boson that subsequently decays into a W-boson pair, where additional jet activity might arise from the production.  $WW+\text{jet}$  production delivers also potential background to new-physics searches, such as supersymmetric particles, because of leptons and missing transverse momentum from the W decays. Besides the process is interesting in its own right, since W-pair production processes enable a direct analysis of the non-abelian gauge-boson self-interactions, and a large fraction of W pairs will show up with additional jet activity at the LHC. Last but not least  $WW+\text{jet}$  at NLO also delivers the real–virtual contributions to the next-to-next-to-leading-order (NNLO) calculation of W-pair production, for which further building blocks are presented in Ref. [7].

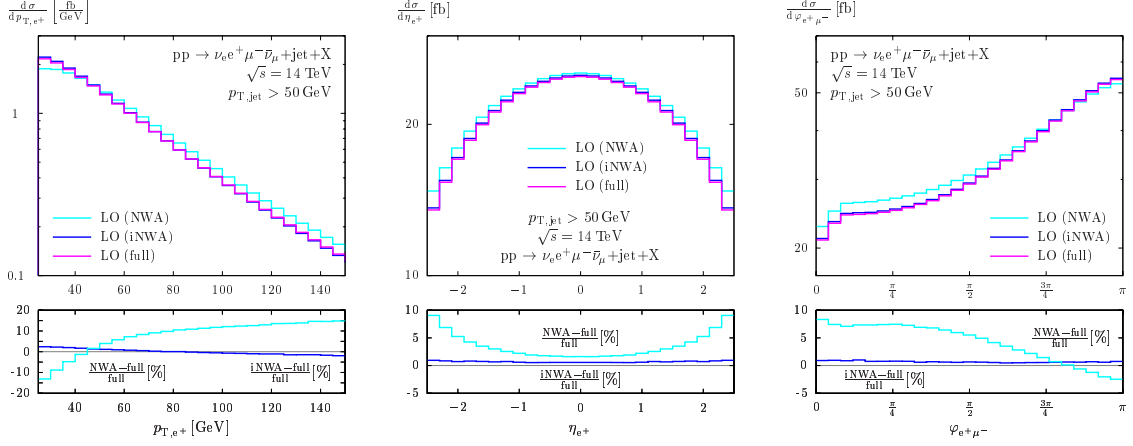

Here we report on the calculation of the process  $pp/p\bar{p} \rightarrow W^+W^- + \text{jet} + X$  in NLO QCD including leptonic W-boson decays. Results of this calculation have been published in Refs. [8, 9]. Parallel to our work, another NLO study [10] of  $pp \rightarrow W^+W^- + \text{jet} + X$  at the LHC appeared. Moreover, NLO QCD corrections to the related processes  $pp \rightarrow W\gamma + \text{jet} + X$  [11] and  $pp \rightarrow ZZ + \text{jet} + X$  [12] have been calculated recently.

## 2. Details of the NLO calculation

At leading order (LO), hadronic  $WW+\text{jet}$  production receives contributions from the partonic processes  $q\bar{q} \rightarrow W^+W^-g$ ,  $qg \rightarrow W^+W^-q$ , and  $g\bar{q} \rightarrow W^+W^-\bar{q}$ , where  $q$  stands for up- or down-type quarks. Note that the amplitudes for  $q = u, d$  are not the same, even for vanishing light-quark masses. All three channels are related by crossing symmetry.

The leptonic W decays are implemented by means of an improved narrow-width approximation (NWA) that treats the W bosons as on-shell particles, but keeps the spin correlations between production and decay processes. In this way, a significantly better approximation of the full calculation is achieved, which can be read off the comparison of the sample LO distributions in Figure 1.

In order to prove the correctness of our results we have evaluated each ingredient twice using independent calculations based—as far as possible—on different methods, yielding results in mutual agreement.

**Figure 1:** Comparison of W-decay descriptions in the distributions of the transverse momentum of  $e^+$  (left plot), the pseudo-rapidity of  $e^+$  (central plot), and the azimuthal angle between the two decay leptons (right plot). The LO cross sections are evaluated at  $\mu = \mu_{\text{fact}} = \mu_{\text{ren}} = M_W$  for the full calculation, the naive NWA, and the improved NWA. (Taken from Ref. [9].)

## 2.1 Virtual corrections

*Version 1* of the virtual corrections is essentially obtained as for the related processes of  $t\bar{t}H$  [13] and  $t\bar{t}+\text{jet}$  [14] production. The Feynman diagrams are generated with *FeynArts* 1.0 [15] and further processed with in-house *Mathematica* routines, which automatically create an output in *Fortran*. The IR divergences (soft and collinear) are analytically separated from the finite remainder in terms of triangle subdiagrams, as described in Refs. [13, 16]. This separation, in particular, allows for a transparent evaluation of so-called rational terms that originate from  $D$ -dependent terms multiplying IR divergences, which appear as single or double poles in  $\epsilon$ . As generally shown in Ref. [4], after properly separating IR from UV divergences such rational terms originating from IR divergences completely cancel; this general result is confirmed in our explicit calculation. For the results presented in Ref. [8], the pentagon tensor integrals were directly reduced to box integrals following Ref. [17], while box and lower-point integrals were reduced à la Passarino–Veltman [18] to scalar integrals. This procedure completely avoids inverse Gram determinants of external momenta in the reduction step from 5-point to 4-point integrals, but the reduction of box and lower-point tensor integrals involves such inverse determinants via the Passarino–Veltman algorithm. Although these inverse determinants jeopardize the numerical stability in regions where such determinants are small, sufficient numerical stability was already achieved. Meanwhile the tensor reduction has been further improved using the methods of Ref. [19]. The scalar one-loop integrals are either calculated analytically or using the results of Refs. [20, 21, 22].

*Version 2* of the evaluation of loop diagrams starts with the generation of diagrams and amplitudes via *FeynArts* 3.4 [23] which are then further manipulated with *FormCalc* 6.0 [24] and eventually automatically translated into *Fortran* code. The whole reduction of tensor to scalar integrals is done with the help of the *LoopTools* library [24], which employs the method of Ref. [17] for the 5-point tensor integrals, Passarino–Veltman [18] reduction for the lower-point tensors, and the *FF* package [25, 26] for the evaluation of regular scalar integrals. The dimensionally regularized soft or collinear singular 3- and 4-point integrals had to be added to this library. To this end, the

**Figure 2:** Scale dependence of the  $WW+\text{jet}$  cross sections with  $W$  decays included and further cuts applied according to Ref. [9]. For the LHC setup, the results are given for  $p_{T,\text{jet}} > 100\text{GeV}$  (left plot). For the Tevatron we show results for  $p_{T,\text{jet}} > 50\text{GeV}$  (right plot).

explicit results of Ref. [16] for the vertex and of Ref. [27] for the box integrals (with appropriate analytical continuations) are taken.

## 2.2 Real corrections

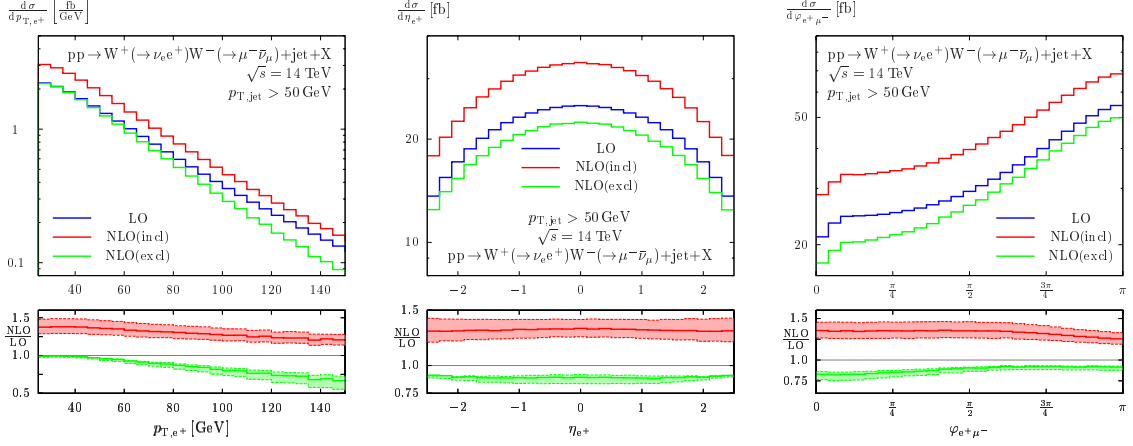

The matrix elements for the real corrections are given by the processes  $0 \rightarrow W^+W^-q\bar{q}g$  and  $0 \rightarrow W^+W^-q\bar{q}q'\bar{q}'$  with a large variety of flavour insertions for the light quarks  $q$  and  $q'$ . The partonic processes are obtained from these matrix elements by all possible crossings of quarks and gluons into the initial state. The evaluation of the real-emission amplitudes is performed in two independent ways. In one approach we apply the Weyl–van-der-Waerden formalism (as described in Ref. [28]). The other one is based on *Madgraph* [29] generated code. Both evaluations employ (independent implementations of) the dipole subtraction formalism [30] for the extraction of IR singularities and for their combination with the virtual corrections.

In one calculation the phase-space integration is performed by a multi-channel Monte Carlo integrator [31] with weight optimization [32] written in *C++*, which is constructed similar to *RacoonWW* [33, 34]. The second calculation uses a simple mapping where the phase space is generated from a sequential splitting.

## 3. Numerical results

We consistently use the CTEQ6 [35] set of parton distribution functions (PDFs), i.e. we take CTEQ6L1 PDFs with a 1-loop running  $\alpha_s$  in LO and CTEQ6M PDFs with a 2-loop running  $\alpha_s$  in NLO. The complete setup we used for our numerical calculations is precisely defined in Ref. [9], where a large variety of additional results is provided.

Figure 2 shows the scale dependence of the NLO cross section for the LHC and the Tevatron. The QCD corrections stabilize the LO prediction for the  $WW+\text{jet}$  cross section considerably with respect to a variation of the factorization and renormalization scales which we identify with each other. At the LHC, this stabilization of the prediction, however, requires a veto on a second hard jet. Otherwise the production of final states with  $WW+2\text{jets}$ , which yields a LO component of the NLO correction, introduces again a large scale dependence. In Figure 3 a sample of NLO distributions is

**Figure 3:** Differential cross sections for  $WW+\text{jet}$  with decays included in the improved NWA at the LHC: The LO and NLO distributions are shown for  $\mu = \mu_{\text{fact}} = \mu_{\text{ren}} = M_W$ . The distributions of the transverse momentum of  $e^+$  (left plot), the pseudo-rapidity of  $e^+$  (central plot), and the azimuthal angle between the two decay leptons (right plot) are depicted. The bands in the  $K$ -factors refer to a variation of  $\mu$  by a factor of 2 in the NLO quantities. (Taken from Ref. [9].)

provided for the LHC setup. At the LHC the pseudo-rapidity distributions in the dominant region and also the distributions in the angles between the two charged leptons have an almost constant  $K$ -factor of about 1.3 (inclusive cross-section definition); for the exclusive cross-section definition the corrections are even smaller and rather close to 1. The  $p_T$  spectra, on the other hand, show a much more phase-space-dependent  $K$ -factor with the exclusive cross-section definition showing an even larger dependence than the inclusive one. This is not surprising since the  $p_T$  introduces an additional scale which could introduce potentially large logarithms which are badly treated by a constant renormalization scale. At the Tevatron our findings are similar [8, 9]. We note that the almost constant  $K$ -factor which holds for a remarkable number of distributions has also been observed in Ref. [10].
