The Second Catalog of Blazars and other AGNs detected by the \textit{Fermi}/LAT (2LAC) includes about 1100 sources, 886 of which comprise the Clean Sample. The general properties of the different populations of sources classified according to the strength of their emission lines (FSRQs, BL Lacs) or the estimated position of the synchrotron peak are reviewed. The 2LAC includes 90\% of the known TeV-detected AGNs. Features of these sources in the GeV range are discussed.
1. Introduction

Since the launch of the Fermi satellite in June 2008, the Fermi-LAT has opened a new era in high-energy astrophysics. The LAT instrument, built by an international consortium of institutions from the USA, Italy, France, Sweden and Japan, is composed of 16 elements each including a tracker and a calorimeter. The tracker, enabling the direction of the incident photon to be reconstructed, consists of alternate layers of silicon strips and Tungsten conversion foils where the photon preferentially converts into an electron-positron pair. The calorimeter comprising eight layers of CsI crystals, about one radiation length-thick each, measures the energy of the electromagnetic shower initiated by the gamma-ray photon. The whole instrument is surrounded by an anticoincidence detector consisting of 89 plastic scintillator tiles, allowing a discrimination between gamma-ray photons and background charged cosmic rays. The LAT energy range is 20 MeV–300 GeV, the high-energy end corresponding to a statistical shortage of detected photons. The point-spread function of the detector is strongly energy dependent. It is governed by the multiple scattering of the initial electron-positron pair at low energy and by the pitch of the silicon strips at high energy. The field of view is 2.4 sr, i.e., about 20% of the entire sky is covered at a given time. The orbit altitude is 565 km, corresponding to a period of about 91 minutes. The orbit inclination is 25.6°. In survey mode, the instrument rocks by about 50° alternatively south and north over one orbit, enabling the whole sky to be scanned every 3 hours with roughly uniform exposure. The mission has a guaranteed 5-year livetime, extending till 2013. At the end of that period, a 5-year source catalog will be produced. The instrument was designed with a target livetime of 10 years, with no consumable aboard. So far the deterioration rate of the detector has been extremely slow, with fewer than 400 (out of 880 000) tracker strips disabled. Every 2 years (starting in 2012) a review panel will issue recommendations about extending the support to the mission, the first examined period being 2013–2014.

2. The variable sky seen by the LAT

The LAT presents many assets regarding AGN Science. Its unprecedented sensitivity, almost uniform at high galactic latitude, makes it very suitable to study populations of extragalactic objects. The continuous scan in survey mode allows alerts to be issued shortly after transient or new flaring sources are detected and enables well source monitoring on time scales ranging from months down to a few hours. One of the most spectacular examples concerns the flares of the blazar 3C 454.3 (Fig. 1), which reached a record flux level above 100 MeV of \(8 \times 10^{-5} \text{ ph cm}^{-2} \text{s}^{-1}\), \((\gamma\text{-ray luminosity} > 10^{50} \text{ erg/s})\) showing variability time scales of a few hours [1].

Another breakthrough arises from the Fermi/LAT large energy range extending into the 10-100 GeV domain, which was previously little explored. This feature has allowed new spectral features at high energy to be discovered and has also enabled the identification of potential candidates of TeV sources, effectively leading to several discoveries by ground-based Cherenkov detectors.

At the time of this conference, about 130 Astronomers Telegrams (ATels) have been issued on the basis of LAT data, of which 120 concerned AGNs. The alert threshold is a flux above 100 MeV greater than \(10^{-6} \text{ ph cm}^{-2} \text{s}^{-1}\), but other considerations like a significant flux rise with respect to the average flux, the detectability at TeV energies for a known source or the rarity of a transient
As EGRET demonstrated that the extragalactic γ-ray sky was dominated by blazars, there were great expectations concerning advances in blazar and AGN science from the Fermi/LAT. Many of these expectations have been or are about to be fulfilled. In the following, recent advances concerning Fermi/LAT blazar populations and their different properties are presented.

3. Blazar Populations

The Second Catalog of Active Galactic Nuclei Detected by the Fermi/LAT [4], referred to as 2LAC in the following is a spinoff of the Fermi/LAT Second Source Catalog (2FGL) [5] based on data accumulated over the first 24 months of sky survey. A first list of Fermi/LAT-detected AGNs using 3 months of data and including 106 high-confidence sources, called the LAT Bright AGN Sources (LBAS) [6] was released in early 2009. The First LAT AGN Catalog (1LAC) [7] was released in the Fall of 2010. It made use of 11 months of data and included 709 sources.

The mean 95% containment radius is 0.15° for the high-latitude 2FGL sources. The association of a given source with an AGN is based on spatial coincidence following three different approaches described in [4]. Different catalogs were used for this purpose including the Combined Radio All-sky Targeted Eight GHz Survey (CRATES) [8], the Candidate Gamma-Ray Blazar Survey (CGaBS) [9] and the Roma-BZCat [10]. This procedure leads to the association of 1017 sources at |b| > 10° (with association probability determined from Monte-Carlo simulations \( P > 0.8 \)) corresponding to 991 distinct γ-ray sources (out of 1319 2FGL sources lying in this galactic-latitude range). A total of 886 sources belong to the “Clean Sample” meeting the following conditions: no double associations and no anomaly observed in the association or detection procedures. Only roughly 12 associations are expected to be spurious in that sample. The validity

![Figure 1: Daily light curve of 3C454.3 measured with the Fermi-LAT since launch. Inset: Historical light curve. Black points are from EGRET [2] and blue points are from AGILE [3].](image-url)
of the procedure is confirmed by the good agreement of the actual distribution of angular separation between \(\gamma\)-ray sources and their AGN counterparts with theoretical expectations.

Although the fraction of identification of high-galactic sources is fairly large (\(\approx 75\%\)), some identifications are clearly missed as a significant asymmetry between northern and southern galactic hemispheres is observed (only 38\% of BL Lacs are observed at \(b < -10^\circ\), while little asymmetry is observed for the whole 2FGL sources), manifesting the incompleteness of the parent catalogs.

The classification in terms of Flat-Spectrum Radio Quasars (FSRQs) and BL Lap-type objects (BL Lacs) is conventionally based on the strength of the emission lines. This classification has been used in both the 1LAC and the 2LAC. In addition, a more refined classification based on the source spectral energy distribution (SED) and dealing with the location of the synchrotron peak \(v_{\text{syn}}\) has been carried out by using archival data at lower wavelengths, more precisely \(\alpha_{\text{ro}}\) and \(\alpha_{\text{ox}}\), the radio-to-optical and optical-to-X-ray spectral slopes. The empirical relation between \((\alpha_{\text{ro}}, \alpha_{\text{ox}})\) and \(v_{\text{syn}}\) was derived from a set of 48 high-quality, simultaneous SEDs of \(\gamma\)-ray blazars [11]. Sources were classified as low-, intermediate- or high-synchrotron peaked sources (referred to as LSPs, ISPs, HSPs respectively) if \(\log(v_{\text{syn}}/Hz) < 14\), \(14 < \log(v_{\text{syn}}/Hz) < 15\) or \(\log(v_{\text{syn}}/Hz) > 15\) respectively.

The census of sources in the 2LAC Clean Sample is as follows: 310 FSRQs, 395 BL Lacs (44\% of which have a measured redshift), 24 other AGNs, 157 of unknown type. The more frequent detections of BL Lacs relative to FSRQs is in sharp contrast with the situation encountered with EGRET [2] where FSRQs outnumbered BL Lacs by a factor \(\approx 3\). This is probably primarily related to the larger sensitivity at high energy of the LAT, as most BL Lacs have harder spectra than FSRQs as discussed below. Moreover, the LAT is far more sensitive to multi-GeV photons than was EGRET, which lost sensitivity above several GeV due to self-vetoing effects.

The 24 non-blazar objects in the 2LAC Clean Sample include 8 misaligned AGNs, 4 Narrow-Line Seyfert 1 galaxies, 10 AGNs of other types and 2 starburst galaxies. A total of 45 (out of 599) 1LAC Clean Sample sources are missing in 2LAC. Due to variability, misaligned AGNs as 3C 78, 3C 111 and 3C 120 don’t make the significance cut over the 24 month period covered by the 2LAC while they were present in the 1LAC. Fornax A and Cen B are new entries relative to 1LAC.

All (except for a few) FSRQs for which \(v_{\text{syn}}\) can be estimated from archival data are of the LSP type. For BL Lacs, the breakdown is 61 LSPs, 81 ISPs, and 160 HSPs. In line with the trend
Figure 3: Peak frequency of the SED synchrotron component vs. photon spectral index for FSRQs (red) and BL Lacs (green: LSPs, cyan: ISPs, blue: HSPs) in the 2LAC Clean Sample.

already observed in the BL Lac/FSRQ ratio, HSPs constitute the most abundant subclass.

The LAT-detected FSRQs all exhibit soft $\gamma$-ray spectra while BL Lacs are more diverse as illustrated in Figure 3, showing the spectral photon index measured with the LAT plotted versus the estimated position of the synchrotron peak.

3.1 Redshift distribution

The redshift distributions for FSRQs and BL Lacs in the Clean Sample are presented in Figure 4. Note that only 44% of 2LAC BL Lacs have measured redshifts. This is notably worse than for LBAS, in which 29 out of 42 (69%) BL Lacs had measured redshifts, but similar to 1LAC (42%). The highest redshift for a high-confidence 2LAC FSRQ is $z = 3.10$. For comparison, the maximum redshift in both CGRaBS and Roma-BZCAT is for an FSRQ with $z > 5$. No strong evidence for a new population of misaligned FSRQs emerging at lower redshifts is found.

It is interesting to compare the redshift distribution of the LAT blazars (in particular, the FSRQs) with that of the objects detected by BAT on Swift [12]. In the BAT survey, 40% of all FSRQs have $z > 2$, and the distribution extends to $z \sim 4$. This behavior may be indicative of a shift in the SED peak frequencies toward lower values (i.e., a “redder” SED) for blazars at high redshifts. Indeed, the jets of the high-redshift BAT blazars are found to be more powerful than those of the LAT blazars and are among the most powerful known [13]. The peak of the inverse Compton flux for these objects, estimated to be in the MeV or even sub-MeV range, is located closer to the BAT band than to the LAT band, and the LAT instead samples the cutoff region of the inverse Compton spectrum.

The photon spectral index is plotted against redshift in Figure 5. For FSRQs, no significant evolution is visible. This behavior is compatible with what was previously observed for LBAS and 1LAC. The attenuation effect of the extragalactic background light (EBL) would tend to introduce spurious evidence of evolution, but the soft spectra of FSRQs and the common presence of spectral breaks at a few GeV [14] both minimize this effect. A stronger evolution is seen for BL Lacs:
hard sources are mostly located at low redshifts, while most high-redshift sources are softer than average (though it is important to bear in mind that most BL Lacs do not have measured redshifts).

3.2 Spectral break

While all AGNs spectra measured with EGRET were consistent with single power law distributions, the extended energy range covered by the Fermi/LAT has enabled to discover the presence of a spectral break at a few GeV for bright LBAS FSRQs and some LSP-/ISP-BL Lacs [14]. So far, no break has ever been found in the spectrum of any bright HSP-BL Lacs, while if present it would have easily be detectable given the relative hardness of these sources. The first evidence for such feature was found in 3C 454.3 [15], which is still so far the best studied case thanks to its high recent brightness. A good model to the data is a broken power law with a break energy of 2.5 GeV and a change in spectral slope of about 1. The break origin is still unknown, several possibilities are being actively discussed: feature in the underlying electron energy distribution [15], superposition of two external Compton components [16], attenuation due to pair-production with He II line photons from the broad-line region [17].

In the 2LAC Clean Sample, 69 bright sources (57 FSRQs and 12 BL Lac LSPs) show very significant curvature. One must keep in mind that in order to show a high curvature index a source
needs both to have a spectrum deviating from a power-law distribution and be bright enough so that the observed deviation is statistically significant. Some fainter sources thus probably do exhibit curved spectra as well.

4. Luminosity Distributions

Figure 6 shows the photon spectral index plotted against the $\gamma$-ray luminosity. This correlation has been widely discussed in the context of the “blazar divide” [18]. It is important to bear in mind important caveats when interpreting this correlation. For instance, more than half of the BL Lacs lack measured redshifts. Strongly beamed emission can overwhelm the atomic line radiation flux and might preferentially arise from high luminosity, high redshift BL Lac objects [19]. These would then be absent in the spectral index/luminosity diagram (Fig. 6) and skew the correlation. Until the redshift incompleteness, the nature of the unassociated sources in the 2LAC, and underlying biases introduced by using different source catalogs are resolved, conclusions about the blazar sequence [20, 21] and the blazar divide [18] remain tentative. It is also worthwhile to mention that the correlation visible for blazars in Figure 6 is very weak if FSRQs and BL Lacs are considered separately.

4.1 GeV-TeV connection

Out of 45 AGNs detected in the TeV regime and listed in the TeVCat catalog\(^1\), 39 are in 2LAC and 34 are in the Clean Sample. *Fermi*-LAT was implicated in the detection of nine of these objects. Please note that only 13 TeV AGNs display significant variability in the GeV range. For

Figure 6: Photon spectral index vs. $\gamma$-ray luminosity for the different AGN classes (solid circles: FSRQs, squares: LSP-BL Lacs, triangles: ISP-BL Lacs, crosses: HSP-BL Lacs, stars: radio galaxies) in the Clean Sample.

Figure 7: The difference in photon index between that measured by Fermi LAT and that reported in the TeV regime, $\Delta \Gamma \equiv \Gamma_{\gamma} - \Gamma_{\gamma}$, for the 19 GeV-TeV AGN with reliable redshifts and reported TeV spectra as a function of their redshift.

The 2LAC Clean Sample, the largest subclass in the TeV AGNs (18) is the HSPs but there also 6 ISPs, 5 LSPs and 5 AGNs whose SED class remains unclassified using the technique described above. The mean photon index of the 2LAC sources associated with the TeV AGNs is $1.87 \pm 0.27$, while the mean photon index of the Clean 2LAC Sample is $2.13 \pm 0.30$, indicating that those AGNs which are detected at TeV are, in general, harder than the majority of the 2LAC sources at Fermi-LAT energies. For eight TeV AGNs in the Clean Sample; the Fermi LAT spectra are best fit by a LogParabola. In many cases, there is a significant difference between the Power-law spectral indices measured by Fermi LAT, $\Gamma_{\gamma}$, and by the Cherenkov telescopes, $\Gamma_{\gamma}$, indicating that the
AGNs with the Fermi-LAT

Benoit Lott

spectrum undergoes a break somewhere in the γ-ray regime (Fig. 7). However, most of the TeV spectra have not been measured simultaneously with the GeV spectra, and caution is advised when comparing the spectra in detail. The mean break index is $\langle \Gamma \rangle = 1.3$. An apparent deficit of sources with small $\Delta \Gamma$ is observed at high redshift which may partly be the effects of pair production with the EBL, which is expected to introduce a redshift-dependent steepening into the TeV spectra of extragalactic objects.

5. Conclusion

In the long-run, the Fermi-LAT will remain extremely valuable for monitoring variable sources or detecting transient events, as the sensitivity roughly scales as the square root of time while the number of detected transients scales linearly with time. Certainly, the (partial) overlap with CTA will be an important factor to keeping the mission up and running. Unfortunately, no successor for the Fermi mission with similar or better performance is currently under development.

6. Acknowledgements

The Fermi LAT Collaboration acknowledges generous ongoing support from a number of agencies and institutes that have supported both the development and the operation of the LAT as well as scientific data analysis. These include the National Aeronautics and Space Administration and the Department of Energy in the United States, the Commissariat à l’Energie Atomique and the Centre National de la Recherche Scientifique / Institut National de Physique Nucléaire et de Physique des Particules in France, the Agenzia Spaziale Italiana and the Istituto Nazionale di Fisica Nucleare in Italy, the Ministry of Education, Culture, Sports, Science and Technology (MEXT), High Energy Accelerator Research Organization (KEK) and Japan Aerospace Exploration Agency (JAXA) in Japan, and the K. A. Wallenberg Foundation, the Swedish Research Council and the Swedish National Space Board in Sweden.
