We discuss diphoton semi(exclusive) production in ultraperipheral PbPb collisions at energy of $\sqrt{s_{NN}} = 5.5$ TeV (LHC). The nuclear calculations are based on equivalent photon approximation in the impact parameter space. The cross sections for elementary $\gamma\gamma \rightarrow \gamma\gamma$ subprocess are calculated including two different mechanisms: box diagrams with leptons and quarks in the loops and a VDM-Regge contribution with virtual intermediate hadronic excitations of the photons. We got relatively high cross sections in PbPb collisions (306 nb). This opens a possibility to study the $\gamma\gamma \rightarrow \gamma\gamma$ (quasi)elastic scattering at the LHC. We find that the cross section for elastic $\gamma\gamma$ scattering could be measured in the lead-lead collisions for the diphoton invariant mass $W_{\gamma\gamma} \approx 15 - 20$ GeV.

XXIV International Workshop on Deep-Inelastic Scattering and Related Subjects
11-15 April, 2016
DESY Hamburg, Germany

*I would like to thank the DIS2016 Organizing Committee for a possibility to present our results.
†Speaker.
1. Introduction

In classical Maxwell theory photons/waves/wave packets do not interact. In contrast, in quan-
tal theory they can interact via quantal fluctuations. So far only inelastic processes, i.e. production
of hadrons or jets via photon-photon fusion could be measured e.g. in $e^+e^-$ collisions or in ul-
traperipheral collisions (UPC) of heavy-ions. It was realized only recently that ultraperipheral
heavy-ions collisions can be also a good place where photon-photon elastic scattering could be
tested experimentally [1, 2].

2. Theory

2.1 Elementary cross section

![Diagram of light-by-light scattering mechanisms](image)

Figure 1: Light-by-light scattering mechanisms with the lepton and quark loops (first panel) and for the
intermediate W-boson loop (second panel). Third panel represents VDM-Regge mechanism and the last
panel is for two-gluon exchange.

One of the main ingredients of the formula for calculation of the nuclear cross section is ele-
mentary $\gamma\gamma \rightarrow \gamma\gamma$ cross section. The lowest order QED mechanisms with elementary particles are
shown in two first diagrams of Fig. 1. The first diagram is for lepton and quark loops and it dom-
inates at lower photon-photon energies ($W_{\gamma\gamma} < 2m_W$) while the next diagram is for the $W$ (spin-1)
boson loops and it becomes dominant at higher photon-photon energies ([3, 4]). The one-loop box
amplitudes were calculated by using the Mathematica package FormCalc and the LoopTools
library. We have obtained good agreement when confronting our result with those in [5, 6, 3].
Including higher-order contributions in the context of elastic scattering seems to be interesting.
In Ref. [6] the authors considered both the QCD and QED corrections (two-loop Feynman dia-
grams) to the one-loop fermionic contributions in the ultrarelativistic limit ($\hat{s}, |\hat{t}|, |\hat{u}| \gg m_f^2$). The
corrections are quite small numerically so the leading order computations considered by us are
satisfactory. In last two diagrams of Fig. 1 we show processes that are the same order in $\alpha_{em}$ but
higher order in $\alpha_s$. In this article we consider process shown in the third panel where both photons
fluctuate into virtual vector mesons (here we include three different light vector mesons: $\rho, \omega, \phi$).
The last diagram shows the mechanism which is formally three-loop type but we will not consider
here the contribution of this mechanism. The exact calculations for this process in the context of
elementary $\gamma\gamma \rightarrow \gamma\gamma$ and nuclear $AA \rightarrow AA\gamma\gamma$ cross section were done in Ref. [7].

2.2 Nuclear cross section

The general situation for the $AA \rightarrow AA\gamma\gamma$ reaction is sketched in Fig. 2. In our equivalent
photon approximation (EPA) in the impact parameter space, the total (phase space integrated) cross
section is expressed through the five-fold integral (for more details see e.g. [8])

\[
\sigma_{A_1A_2\rightarrow A_1A_2\gamma\gamma}(\sqrt{s_{A_1A_2}}) = \int \sigma_{\gamma\gamma\rightarrow \gamma\gamma}(W_{\gamma\gamma}) N(\omega_1, \mathbf{b}_1)N(\omega_2, \mathbf{b}_2)S_{\text{abs}}(\mathbf{b})^2 2\pi b_1 b_2 d\omega_1 d\omega_2 W_{\gamma\gamma}^2 dW_{\gamma\gamma} dY_{\gamma\gamma},
\]

where \( N(\omega, \mathbf{b}) \) are photon fluxes, \( W_{\gamma\gamma} = \sqrt{4\omega_1 \omega_2} \) and \( Y_{\gamma\gamma} = (y_{\gamma_1} + y_{\gamma_2})/2 \) is an invariant mass and a rapidity of the outgoing \( \gamma\gamma \) system. Energy of photons is expressed through \( \omega_{1/2} = W_{\gamma\gamma}/2 \exp(\pm Y_{\gamma\gamma}) \). \( \mathbf{b}_1 \) and \( \mathbf{b}_2 \) are impact parameters of the photon-photon collision point with respect to parent nuclei 1 and 2, respectively, and \( \mathbf{b} = \mathbf{b}_1 - \mathbf{b}_2 \) is the standard impact parameter for the \( A_1A_2 \) collision.

The photon flux \( (N(\omega, \mathbf{b})) \) is expressed through a nuclear charge form factor. In our calculations we use two different types of the form factor. The first one, called here realistic form factor, is the Fourier transform of the charge distribution in the nucleus and the second one is a monopole form factor which leads to simpler analytical results. More details can be found find e.g. in [2, 8].

3. Results

![Figure 3: Elementary and nuclear cross section for light-by-light scattering.](image)

The elementary angle-integrated cross section for the box and VDM-Regge contributions is shown in the first panel of Fig. 3 as a function of the photon-photon subsystem energy. Lepton
and quark amplitudes interfere enhancing the cross section. For instance in the 4 GeV < W < 50 GeV region, neglecting interference effects, the lepton contribution to the box cross section is by a factor 5 bigger than the quark contribution. Interference effects are large and cannot be neglected. At energies W > 30 GeV the VDM-Regge cross section becomes larger than that for the box diagrams. The right panel of Fig. 3 shows results for nuclear collisions for the case of realistic charge density (red lines) and monopole form factor (blue lines). The difference between the results becomes larger with larger values of the kinematical variables. The cross section obtained with the monopole form factor is somewhat larger.

![Figure 4: Contour representation of two-dimensional (dσ/dyγ1dyγ2) in nb) distribution in rapidities of the two photons in the laboratory frame for box (left panel) and VDM-Regge (right panel) contributions.](image)

If we try to answer the question whether the reaction can be measured with the help of LHC detectors then we have to extend Eq. (2.1) by extra integration over additional parameter related to angular distribution for the subprocess [2]. Fig. 4 shows two-dimensional distributions in photon rapidities in the contour representation. The calculation were done at the LHC energy √sNN = 5.5 TeV. Here we impose cuts on energies of photons in the laboratory frame (Eγ > 3 GeV). Very different distributions are obtained for boxes (left panel) and VDM-Regge (right panel). In both cases the influence of the imposed cuts is significant. In the case of the VDM-Regge contribution we observe as if non-continuous behaviour which is caused by the strong transverse momentum dependence of the elementary cross section (see Fig. 4 in Ref. [2]) which causes that some regions in the two-dimensional space are almost not populated. Only one half of the (yγ1, yγ2) space is shown for the VDM-Regge contribution. The second half can be obtained from the symmetry around the yγ1 = yγ2 diagonal. Clearly the VDM-Regge contribution does not fit to the main detector (−2.5 < yγ1, yγ2 < 2.5) and extends towards large rapidities. In the case of the VDM-Regge contribution we show much broader range of rapidity than for the box component. We discover that maxima of the cross section associated with the VDM-Regge mechanism are at |yγ1|, |yγ2| ≈ 5. Unfortunately this is below the limitations of the ZDCs (|η| > 8.3 for ATLAS ([9]) or 8.5 for CMS ([10])).

Finally in Fig. 5 we show numbers of counts in the 1 GeV intervals expected for assumed integrated luminosity: Lint = 1 nb⁻¹ typical for UPC at the LHC. We have imposed cuts on photon-photon energy and (pseudo)rapidities of both photons. It looks that one can measure invariant mass distribution up to Mγγ ≈ 15 GeV.
4. Conclusions

In our recent paper [2] we have studied in detail how to measure elastic photon-photon scattering in ultrarelativistic ultraperipheral lead-lead collisions. The calculations were performed in an equivalent photon approximation in the impact parameter space. The cross section for photon-photon scattering was calculated taking into account well known box diagrams with elementary standard model particles (leptons and quarks) as well as a VDM-Regge component which was considered only recently [2] in the context of $\gamma\gamma \rightarrow \gamma\gamma$ scattering.

Several distributions in different kinematical variables were calculated. Using the monopole form factor we get similar cross section to that found in [1] (after the correction given in Erratum of [1]). Nevertheless, we think that application of realistic charge distribution in the nucleus gives more precise results. We have shown an estimate of the counting rate for expected integrated luminosity. We expect some counts for subprocess energies smaller than $W_{\gamma\gamma} \approx 15\text{--}20 \text{ GeV}$.
