Performance studies for a next-generation optical sensor for IceCube-Gen2

The IceCube-Gen2 Collaboration
E-mail: shimizu@hepburn.s.chiba-u.ac.jp, aya@hepburn.s.chiba-u.ac.jp, alexander.kappes@uni-muenster.de

We present performance studies of a segmented optical module for the IceCube-Gen2 detector. Based on the experience gained in sensor development for the IceCube Upgrade, the new sensor will consist of up to eighteen 4 inch PMTs housed in a transparent pressure vessel, providing homogeneous angular coverage. The use of custom molded optical ‘gel pads’ around the PMTs enhances the photon capture rate via total internal reflection at the gel-air interface. This contribution presents simulation studies of various sensor, PMT, and gel pad geometries aimed at optimizing the sensitivity of the optical module in the face of confined space and harsh environmental conditions at the South Pole.

Online – Berlin, Germany
1. IceCube, IceCube-Upgrade and IceCube-Gen2

The IceCube Neutrino Observatory is a cubic kilometer neutrino telescope deployed in the glacial ice of the South Pole in Antarctica, and aims to observe high energy astrophysical neutrinos. Between depths of 1450 m to 2450 m, 5160 digital optical modules (DOMs) are deployed along 86 strings, and detect Cherenkov light emitted by secondary charged particles produced by the interactions of neutrinos. In the following text, this established project is referred to as IceCube-Gen1.

The IceCube Upgrade array, also known as IceCube-Gen2 Phase-I, consists of approximately 700 newly designed optical sensors and calibration modules, densely embedded near the bottom center of the existing IceCube Neutrino Observatory. The Upgrade array is currently planned to be deployed during 2022/2023 Austral Summer. Two new optical module designs will be employed in the Upgrade: the multi-PMT Digital Optical Module (mDOM) [1] and the Dual optical sensors in an Ellipsoid Glass for Gen2 (D-Egg) [2], both designed to improve the photon detection efficiencies and the calibration capability of the detector. The IceCube Upgrade improves the reconstruction efficiency for few-GeV neutrinos, and will improve knowledge of the properties of scattering in ice, which yields better resolution on the neutrino events.

The IceCube upgrade is to be followed by the construction of the Gen2 array [3]. IceCube-Gen2 will consist of approximately 8 km$^3$ of instrumented ice and an array of approximately 10,000 optical sensors with a horizontal spacing of ~240 m to achieve at least five times better sensitivity than that of IceCube for high energy neutrinos between 100 TeV to 1 PeV [4].

The different science targets goals of each project require different array configurations. Due to the horizontally sparse design of Gen2, maximising the photon collection efficiency of DOMs is particularly important.

2. Requirements and the baseline optical module designs for Gen2

Gen2 will be a major construction effort. Optical sensors will be installed into water-filled holes in the South Pole ice made by a hot water drill, and will be fixed in place when the hole ice refreezes. For a significant cost saving as well as to complete the construction within eight years, the drill hole size is being optimized. This will limit the diameter of optical modules for Gen2 to ≤ 12”, smaller than that of Gen1 DOMs. Regardless of their design, the modules will need to withstand

| Table 1: Information on the various optical modules |
|----------------------------------|--------|----------------|-----------------|----------------|
| Name               | PMT diameter | Number of PMTs | Glass diameter | Glass height |
| Gen1 DOM           | 10 [inch]    | 1              | 330 [mm]       | 330 [mm]      |
| mDOM               | 3.15 [inch]  | 24             | 356 [mm]       | 411 [mm]      |
| D-Egg              | 8 [inch]     | 2              | 300 [mm]       | 534 [mm]      |

Studies for an optical sensor for IceCube-Gen2

Figure 1: Schematic view of the optical modules. Gen-1 DOMs are used for the IceCube array, and mDOM and D-Eggs will be deployed in the IceCube-Upgrade holes. mEgg and LOM–18 are two designs for IceCube Gen2 studied here.

the maximum pressure of 70 MPa during the hole refreezing period, and 13-30 MPa will be the typical pressure after re-freezing. Modules need to be sound against the thermal gradient of 20 °C water during deployment to -9 °C to -40 °C expected during operating conditions. Simulations indicate that optical modules with a three times higher effective area compared to Gen1 DOM and less than ± 20% variation in sensitivity across the angle of photon incidence, will allow us to meet our science goals.

Figure 1 shows the schematic view of the optical modules deployed as IceCube array (a), the modules to be installed in the Upgrade array (b,c) and the modules under investigation for the Gen2 array (d,e). The Gen1 DOM is a highly reliable optical sensor running for more than ten years with an extremely small (≤ 0.5%) post-deployment failure rate. A Gen1 DOM implements a single downward-facing 10 inch photomultiplier tube (PMT), the Hamamatsu R7081-2-MOD, and signals from the PMT are digitized in the readout board placed in the upper hemisphere of the module.

The mDOM for the IceCube Upgrade includes twenty-four 3.15 inch PMTs (Hamamatsu R15458-02) oriented in all directions, providing homogeneous sensitivity to photons. The side of the entrance window of the PMT is covered by an aluminum-coated reflector which improves the effective area by a factor of 20% [1].

The D-Egg, also being used in the IceCube Upgrade, implements two high-quantum efficiency (QE) 8 inch PMTs, the Hamamatsu R5912-100, in an elliptical glass vessel, facing both upward and downward. Because the top and bottom parts of the housing glass curvature are designed to be matched precisely with the R5912 PMT surface curvature of φ131 mm, the actual photocathode area is 20% more than when a flat disk of the same diameter is assumed.

The Long Optical Module (LOM) for Gen2 [5] is designed to fit into the smaller Gen2 holes while maximizing the effective photon sensitive area. The Gen2 hole diameter limits the diameter of the pressure vessel. The height of the housing is limited by the total weight of the module to be less than 26 kg. The optimized LOM modules include sixteen or eighteen 4 inch PMTs\(^1\). The mEgg is another model of the optical module for Gen2 and uses fourteen 4 inch PMTs in the same glass housing as the D-Egg.

\(^1\)Currently, both sixteen and eighteen-PMT designs (LOM–16 and LOM–18) are under investigation.
3. Enlarging the effective photo-sensitive area with gel pad

All existing modules (Gen1 DOM, mDOM, and D-Egg) utilize ultraviolet (UV) transparent silicone elastomers (optical gel) for coupling between the glass vessel surface and PMT photocathodes. The transmittance of the glass and the optical gel is improved for the Upgrade modules compared to that of the Gen1 DOM [2, 6]. For the Gen2 modules, because of the elongated vessel shape, the PMT surfaces are not vertically facing the glass surface. This complicates the module design. Either we have to use a large amount of optical gel fully filling the vessel or we need to come up with a technique to reduce the amount of optical gel, keeping good optical coupling properties.

In the mEgg and LOM, the air gaps between PMTs and the pressure vessel are filled with an optical gel pad. Figures 2a and 2b show a picture of the molded gel pad and its schematic view in the tentative mechanical design of the LOM. The side wall has a conical shape and works as a light collector thanks to the total internal reflection between the boundary of silicone and air.

To determine the optimal shape of the gel pad, we simulated the photon capture probability assuming the geometrical configuration of the mEgg. Using a GEANT4 [7] based optical photon tracking simulator, we injected a 380 nm parallel circular beam (the beam diameter was chosen to be large enough to fully cover the outer dimension of the mEgg) into the model of the mEgg, and calculated the probability that photons will arrive at any of the PMT photocathodes. Figure 3a shows the evaluated photon capture probability for various values of the gel pad opening angle (its definition is shown in Fig. 3b). After integration over the solid angle, we find that the photon capture probability is maximum for opening angles from $60^\circ$ to $80^\circ$.

The increase in photon capture probability with gel pads is due to the total reflection at their conical surface, and it is of importance to experimentally confirm the performance under realistic conditions in terms of control of surface conditions. We molded the gel pad onto a 3.15 inch PMT (the one adopted for the mDOM) as shown in Fig. 2a) and investigated the feasibility of the gel pad scheme. We injected a parallel spot beam (wavelength 468 nm, spot diameter ~ 2 mm) and counted the number of registered photons while scanning with the beam over the photocathode of the PMT. Figure 4 shows the distribution of the obtained number of photons with and without a gel.

\footnote{At the time of writing, we did not have an electrically functional 4 inch PMT.}
Figure 3: (a) Photon capture probability for various configurations of the opening angle as a function of the incident zenith angle of photons. The geometry of the mEgg was assumed. (b) Definition of the opening angle. (c) Definition of the zenith angle.

Figure 4: Distribution of the observed number of photoelectrons measured by a PMT (a) with and (b) without the gel pad. The solid and dashed lines represent the outer radii of the PMT and gel pad, respectively.

pad. This confirmed that the gel pad indeed increases the sensitive region and causes no serious degradation of photon collection efficiency in the central region. For the parallel beam, an increase in effective area of 68% was measured which is close to the 75% estimated by the simulation.
4. Simulation studies of Cherenkov photon sensitivities

4.1 Simulation setup

Figure 5: (a) Tentative design of the hemisphere of the LOM used in simulation. (b) Implementation of the gel pads (blue) and PMTs (red) in the glass. For a half hemisphere, there are three different levels and they are called bottom, middle, and top.

Figure 5 shows the preliminary design of the LOM—18 glass vessel, gel pads, and PMTs implemented in the simulation. The transmittance of the glass and gel pad are assumed to be the same as those of the D-Egg. The opening angles of the gel pads (see Fig. 3b), 20°, 10°, and 70° (from the middle to top), are chosen so as not to overlap with each other. Eighteen 4 inch PMTs are arranged and tilted in the glass as follows: the top PMTs are vertically aligned, the middle PMTs are tilted by 45°, and the bottom PMTs are tilted by 50°. In the current initial simulation studies, other components such as internal structures and electrical boards are neglected, though there is large enough space to fit them within the pressure vessel.

4.2 Effective photo-sensitive area comparisons

The performance of each optical module is evaluated using its effective area. We simulated a parallel circular beam directed at the module, and calculated the effective area by

\[
A(\theta, \phi, \lambda) = \frac{A_0}{N_{\text{gen}}} \sum_{i, \text{hit}} P(\lambda, \vec{r}_i),
\]

where \(\theta\) and \(\phi\) are zenith and azimuth angles of the beam, \(\lambda\) is the wavelength of the generated photons, \(A_0\) is the area of the circular beam, \(N_{\text{gen}}\) is the number of generated photons, \(P(\lambda, \vec{r}_i)\) is the detection efficiency of the PMT for the wavelength of \(\lambda\) at the hit position of \(i\)-th trial, and the summation is over photons which hit on any photocathodes of PMTs.

The comparison of the sensitivity of the individual modules is performed using the effective area at 400 nm. This is a typical wavelength of the incoming Cherenkov photons, since small wavelength photons are preferentially absorbed in the ice. For small distances, the Cherenkov-
Figure 6: Effective area at 400 nm as a function of cosine of zenith angle of incident photons. The downward-facing direction is defined as $\theta = 0$ ($\cos \theta = 1$).

The averaged effective area can be another benchmark:

$$\bar{A}(\theta, \phi) = \frac{\int_{700 \text{ nm}}^{270 \text{ nm}} \int_{700 \text{ nm}}^{270 \text{ nm}} d\lambda \ A(\theta, \phi, \lambda) P(\lambda)}{\int_{700 \text{ nm}}^{270 \text{ nm}} d\lambda \ P(\lambda)}$$

where $P(\lambda)$ is the Cherenkov spectrum, $n$ is the refractive index of ice, and $\beta$ is the velocity of the traversing charged particle, assumed to be 1. Note that $P(\lambda)$ diverges for small wavelengths and $\bar{A}(\theta, \phi)$ depends on the lower cutoff of $\lambda$.

Table 2 summarizes the effective areas of the various optical modules after averaging over $\cos \theta$ and $\phi$. The Cherenkov-averaged values are shown with respect to that of the Gen1 DOM. For both quantities, the eighteen-PMT model of the LOM will exceed the sensitivity of the Gen1 DOM by more than a factor three. Furthermore, if the same QE is available for the 4 inch PMTs as for the D-Egg PMTs, the sensitivity can be improved by another 30%.

* Variation comes from a difference of the treatment of the detection efficiency of PMTs.
† If high quantum efficiency PMT is available, these improve by 30%.

5. Conclusion

To improve the sensitivity to astrophysical neutrinos, IceCube-Gen2 will include approximately 10,000 next-generation optical modules. To achieve the best performance at limited cost, the diameter of the optical modules is required to be ∼ 12". The optimal design resulted in the concept of the Long Optical Module (LOM). The LOM will consist of sixteen or eighteen 4 inch PMTs, gel pads as optical coupler, and a transparent pressure vessel. A gel pad made of UV transparent silicone optical elastomer has a cone-shaped structure and increases the effective area via total internal reflection at its side surface. The concept of this scheme was experimentally confirmed using a parallel beam scan. To compare the effective area and its incident angular dependence for various optical modules, an optical photon simulation was performed. Compared to the Gen1 DOM, the LOM design will improve the effective area by more than a factor of three. The LOM shows high homogeneity with respect to the dependence of the sensitivity on the angle of photon incidence. Furthermore, if the same high-QE PMT as that of D-Egg is available in the future, the gain will further improve by an additional factor of 30%.
