E-mail: lilly.peters@icecube.wisc.edu

After scattering off nuclei in the Sun, dark matter particles can be gravitationally captured by the Sun, accumulate in the Sun’s core and annihilate into Standard Model particles. Neutrinos originating from these annihilations can be detected by the IceCube Neutrino Observatory, located at the South Pole. Due to the non-observation of these neutrinos, constraints on the standard spin-dependent and spin-independent dark matter-nucleon scattering cross sections have been placed. Based on these constraints, we present upper limits on the coupling constants of the non-relativistic effective theory of dark matter-nucleon interactions, including velocity and momentum dependent interactions.

July 12th – 23rd, 2021
Online – Berlin, Germany
1. Introduction

Although there is compelling evidence for the existence of dark matter (DM), its nature remains unknown. To explain observations, a variety of theories provide candidate particles [1]. There are three complementary ways to search for DM - collider searches, direct and indirect detection. Direct detection aims to determine interactions of DM particles with nuclei, typically with the goal of setting constraints on spin-dependent (SD) and spin-independent (SI) interaction terms. However, there are also approaches to cover the full set of operators in a non-relativistic effective theory, including momentum- and velocity-dependent operators [2]. In recent years, there have been several efforts from direct detection experiments like CRESST-II [3], Xenon100 [4], SuperCDMS [5] and DEAP-3600 [6] to constrain the coupling constants of the theory. With the IceCube Neutrino Observatory we are able to set limits via indirect detection based on DM capture in the Sun.

2. Theory

2.1 Effective Theory of Dark Matter-Nucleon Interactions

We will briefly summarize the effective theory of DM-nucleon interactions following [2]. The amplitude for elastic DM-nucleon scattering is restricted by several symmetries. In particular, Galilean invariance imposes that the scattering amplitude can only depend on combinations of the momentum transferred from the nucleon to the DM particle \( q \) and the relative incoming velocity \( \mathbf{v} = \mathbf{v}_\chi - \mathbf{v}_N \) which is the incoming velocity of the DM particle \( \chi \) in the rest frame of the nucleon \( N \). In addition, the interactions must be hermitian, thus it is useful to work with hermitian quantities and to introduce \( \mathbf{v}^\perp = \mathbf{v} + q/2\mu_N \) with the reduced DM-nucleon mass \( \mu_N \). All interaction operators can be written as a combination of \( i\mathbf{q} \), \( \mathbf{v}^\perp \), the DM spin \( S_\chi \) and the nucleon spin \( S_N \). They are listed in table 1 imposing that they are at most linear in \( S_\chi \), \( S_N \) and \( \mathbf{v}^\perp \). It is assumed that the mediating particle has spin 0 or spin 1 and is heavy compared to the momentum transfer.

The interaction Lagrangian has the form

\[
\mathcal{L}_{\text{int}} = \sum_{N=n,p} \sum_{\ell} \frac{e_N^\ell O_i \chi^\pm \chi^- N^+ N^-}{\sqrt{2} j + 1}
\]

(1)

where \( \chi^\pm, N^\pm \) are the fields involving only creation or annihilation fields and \( c_i^\ell \) and \( c_i^n \) denote the coupling constants for protons and neutrons and have mass dimension -2 [7]. Instead of proton and neutron couplings we will present the results in terms of isoscalar \( c^0 = c^p + c^n \) and isovector \( c^1 = c^p - c^n \) couplings.

Forming a Lagrangian from the operators in table 1 and performing a multipole expansion of the nuclear charges and currents lead to six nuclear response operators contributing to the transition probability, namely \( M, \Sigma', \Sigma'', \Phi', \Phi'' \) and \( \Delta \).

Finally the differential cross-section for DM scattering off a nucleon of type N can be written as

\[
\frac{d\sigma_N}{dE_R}(\omega^2, q^2) = \frac{2m_N}{\omega^2} \left[ \sum_{\ell, \ell'} \sum_{k=M, \Sigma', \Sigma''} R_{k,\ell,\ell'}^\ell \left( \frac{q^2}{m_N^2} \right) \frac{q}{m_N^2} W_{k,\ell,\ell'}^\ell \right] + \sum_{k=\Phi', \Phi'' M, \Phi', \Phi'' \Delta \Sigma} R_{k}^\ell \left( \frac{q^2}{m_N^2} \right) W_{k}^\ell \left( \frac{q^2}{m_N^2} \right)
\]

(2)
2. Dark Matter Capture in the Sun

DM particles of the Milky Way DM halo can scatter off nuclei in the Sun and be gravitationally captured if they scatter from a velocity \( \omega \) to a velocity smaller than the local escape velocity \( v_{\odot}^{\text{esc}}(r) \).

The capture rate for nuclei of type N is given by

\[
C_{\text{cap}}^N = n_X \int_0^{R_0} dr \int_0^{\infty} du \ 4\pi r^2 n_N(r) f_\odot(u) \left( \frac{u^2 + v_{\odot}^{\text{esc}}(r)^2}{u} \right) \int_{E_{\min}}^{E_{\max}} dE_R \frac{d\sigma_N}{dE_R} \theta(\Delta E) \tag{3}
\]

where \( u \) is the velocity of the DM particle at \( r \to \infty \) in the solar frame such that \( \omega = \sqrt{u^2 + v_{\odot}^{\text{esc}}(r)^2} \) [7]. We assume that the DM velocities follow a Maxwell-Boltzmann distribution in the galactic frame without a cut-off at the galactic escape velocity. We use \( v_{\odot} = 220 \text{ km/s} \) for the galactic orbital speed in the solar position, and \( \sigma_v = 270 \text{ km/s} \) for the velocity dispersion. To get the total capture rate \( C_{\text{cap}} \), we sum equation (3) for each of the 16 most abundant elements in the Sun. The elemental abundances \( n_X \) are taken from the B16 GS98 model [9]. Furthermore we assume the DM halo number density to be \( n_X = 0.3 \text{ GeV/cm}^3/M_X \). For a discussion of the astrophysical uncertainties see section 4.2.
3. Capture Rate Limits from IceCube Solar Dark Matter Analyses

When DM particles are captured in the Sun, they can sink into the Sun’s core and annihilate into Standard Model final states. Neglecting evaporation yields the following differential equation describing the number of DM particles in the Sun

\[
\frac{dN}{dt} = C_{\text{cap}} - C_{\text{ann}} N^2
\]

with the general solution \( \Gamma_A = \frac{1}{2} C_{\text{cap}} \tanh^2 \left( \sqrt{\frac{C_{\text{cap}}}{C_{\text{ann}}}} t \right) \) [10]. Neutrinos originating from these annihilations can potentially be observed by neutrino telescopes like the IceCube Neutrino Observatory. IceCube is a cubic-kilometer sized neutrino detector installed in the ice at the geographic South Pole between depths of 1450 m and 2450 m, completed in 2010 [11]. Neutrino reconstruction relies on the optical detection of Cherenkov radiation emitted by charged particles produced in the interactions of neutrinos in the surrounding ice or the nearby bedrock.

IceCube searches for an excess of neutrino events correlated with the direction of the Sun in order to detect signatures of Solar DM annihilation. The results published based on three years of data were able to constrain DM-nucleon scattering for three annihilation channels (\( \tau^+ \tau^-, W^+W^-, b\bar{b} \)) for DM masses up to 10 TeV [12]. Recently, utilizing IceCube DeepCore data and new cuts, an updated analysis using seven years of data pushes IceCube sensitivity at the lower energy end of the DM mass range down to 5 GeV (publication under preparation), and also constrains DM annihilating directly to neutrinos.

4. Results

4.1 Capture rates

To calculate the capture rate for each operator, the value of the coupling constant was set to \( c_t = 10^{-3} m_v^2 \) with \( m_v = 246.2 \text{ GeV} \), while all other coupling constants were set to zero. The value is arbitrary as the capture rate is proportional to the coupling constant squared and the ratio of the two will be used as a conversion factor in section 4.3. There are six isotopes that are responsible for the leading contribution for at least one interaction operator in a certain DM mass range, namely \(^1\text{H}, \, ^4\text{He}, \, ^{14}\text{N}, \, ^{16}\text{O}, \, ^{27}\text{Al} \) and \(^{56}\text{Fe} \). The most important isotope for each operator is determined by a compromise between the elemental abundance, the properties of the nuclear response operators and kinematic factors that depend on the DM and the nucleon mass.

4.2 Systematic uncertainties

The most prominent uncertainty in terms of astrophysical uncertainties is the local DM density that we assume to be 0.3 GeV/cm³, a widely-used value [13]. Recent measurements have best-fit values in the range 0.2 - 0.6 GeV/cm³ [13]. The capture rates and the limits in the next section can be adapted to a different density by scaling with the ratio of the two numbers.

The capture process is sensitive to deviations from the assumed Maxwellian velocity distribution. Figure 1 shows the change in capture rate for a range of \( v_\odot \) from 200 to 280 km/s, while \( c_{\sigma_v} \) is set to \( \sqrt{3/2}v_\odot \). Since Operator 7 is dominated by hydrogen, it is sensitive to changes in the velocity distribution earlier (at smaller DM masses) than operator 15, which is dominated by iron.
Another uncertainty is the elemental composition of the sun. Especially the abundance of the respective dominant isotope is important. For a discussion of the uncertainties in the solar model see [9].

IceCube sensitivity to DM annihilation is also impacted by various detector systematics, which are included in the annihilation rate limits and propagate into the upper limits on the coupling constants.

4.3 Limits on the Coupling Constants

We can now use the computed capture rates to convert the capture rate limits from the IceCube analyses described in section 3 into limits on the coupling constants. The results are shown in figure 2 and 3 for isoscalar and isovector interactions. For simplicity we only present results for DM particles with spin $j_{\nu} = \frac{1}{2}$. The limits are compared to the direct detection experiments CRESST-II [3], Xenon100 [4], DEAP-3600 [6], CDMS II and SuperCDMS [5]. All exclusion limits are at 90% confidence level. CRESST-II is not competitive in the considered mass range but provides the strongest constraints below 5 GeV and is thus shown for completeness. A comparison to LUX [14] is not feasible since they present their results in terms of proton/neutron instead of isoscalar/isovector couplings. Because direct detection experiments are restricted to the isotopes in their detectors, they cannot always set constraints on all interaction types. We observe that whether the strongest constraint comes from direct detection or IceCube is highly dependent on the operator. Notably, for Operator 4, 7 and 14 IceCube sets the most stringent limits for a large mass range, for the first two even with the soft channel analysis.

5. Conclusion and Outlook

We have reported upper limits on the isocalar and isovector coupling constants of the non-relativistic effective theory of DM-nucleon interactions for DM particles with spin 1/2. We want to
Figure 2: Exclusion limits on the isoscalar coupling constants at 90% confidence level.
Non-Standard Dark Matter Interactions with IceCube

**Figure 3:** Exclusion limits on the isovector coupling constants at 90 % confidence level.
stress that the theoretical framework presented in section 2.1 is also valid for other spins and that the analysis can easily be extended.

The shown results are based on annihilation rate limits from two previous IceCube analyses, one from 2017 using three years of data [12] and the other from 2021 focussing on the low energy regime (publication under preparation). Including new analyses like [15] could further improve the limits presented here.
